LECTURES ON SURGERY,

DELIVERED AT ST. THOMAS'S
HOSPITAL,

BY THE LATE MR. CLINE;

With Notes.

[THESE lectures were written by Dr. Wilkinson when attending Mr. Cline's lectures, in the years 1787-88-89.

Extract of a letter from Dr. Wilkinson, dated Feb. 6, 1838:—"They (these lectures) are the results of six courses of lectures I attended at St. Thomas's, in 1787, 1788, and 1789; and I am in hopes I did not omit any interesting part of Mr. Cline's valuable observations. The one I had the pleasure of giving you is the repeated corrected copy."]

LECTURE I.

Considerations and Precepts with regard to Operations—Classes into which Operations used to be divided—Modes in which Union is effected—Impediments to Union—Foreign Bodies—Poisoned Wounds (Hydrophobia)—Different kinds of Sutures—The Interrupted Suture—The Quilled Suture (Casarean Section)—Uninterrupted Suture—Gastroraphie.

In every complaint where an operation is required there may be something in the disease to render the operation improper, not only from the state of the part, but from the state of the patient's constitution. The state of the patient's mind should also be attended to, on which depends our success in a great many operations; for some are so timid, that they become so much depressed on our performing a capital operation on them, that it is impossible to support the powers of life; of which I had a very remarkable instance in a patient who had her breast amputated—not usually a hazardous operation. She expired within an hour after, without

any loss of blood, and having had no previous indisposition, only a prodigious reluctance to the performance of the operation. Another remarkable case I heard of in a gentleman who was supposed to have the stone. Desirous of being sounded, this was done for him; and on being informed that there was a calculus, he was exceedingly struck, and said he should never survive. In about five hours afterwards, though there had been no previous indisposition, he expired. When the state of the patient's mind seems to be unfavourable, it is not the mere expression of a fear of the pain that we need apprehend, but the idea of which they are prepossessed, that they shall die under the operation, or very soon afterwards; for some are very apprehensive of the pain they shall suffer during the operation, but are not afraid of their life,—this is not so material.

Before any capital operation is performed, the patient or his friends should be apprised of every circumstance respecting it, as far as concerns themselves, whether it be hazardous to life or to the part (for in all capital operations there must be some uncertainty in the event); then, of course, the friends are satisfied even if it be not attended with success. In many cases it may be improper to tell the patient himself all the hazard he runs; still the friends should be apprised of it. On this account it is preferable to have a consultation before any capital operation is performed, as the event is so uncertain; thus you will not be so liable to censure if any thing unfortunate should occur. It is also better for a surgeon not to undertake any operation alone, though ever so able; for if unassisted, and any thing unfavourable turns out, the parties will be apt to think it was not done in the best manner: this more particularly regards private practice. Before we operate we should consider every circumstance of the case

previously in our minds, which is often attended with considerable advantage, and probably we will be much less embarrassed if any thing unfavourable turns out, than if it had not been thought of before, particularly with such as are not in the habit of operating. Likewise, before the operation every thing necessary should be at hand, otherwise perhaps in the middle of it something is wanting which cannot immediately be had, and which retards the operation, is very distressing to the patient, and even sometimes dangerous. Those who are not in the habit of operating should endeavour to operate slowly, *not considering the time it shall take, but in what way it can best be done*: every one, indeed, ought to do this. An operation is always well performed provided it is well executed, be the time what it will. In operations where the most mischief has been done, it has been always with the aim of getting it speedily finished. Sometimes unforeseen accidents occur, which those not in the habit of operating have not before seen. In such cases it is necessary sometimes to pause in the middle of an operation, and consider what should be done. The agitation which takes place in many during an operation is in some degree constitutional; it happens almost to every one at the first operation. There is a natural horror in the idea of cutting living flesh; however, by the frequency of operating, and endeavouring to perform slowly, it may be in a great degree removed, though often not entirely.

Surgical authors, in treating of operations, very frequently divide them into classes, particularly the ancients; and Le Dran is the last of them who has followed this method. He divides them into four classes or heads, viz. synthesis, diæresis, exæresis, and prothesis, including under these all the operations in surgery. By synthesis is meant all such as tend to the union of parts, as in making the various sutures in the operation of the hare-lip; also, the replacing of parts which have been displaced, as in hernia. Diæresis is the separation of parts that were united, as in every incision. Exæresis is the complete removal of parts, as in amputation, lithotomy, extracting cataracts, removing tumors, &c. Prothesis signifies the adding of parts to the body; but this is merely a mechanical performance, except in one instance, viz., the transplanting of teeth. This general division does not seem to be attended with any advantage, or to assist at all in the explanation of the subject; therefore Mr. Sharpe, who has written well on this subject, has entirely laid it aside—a plan which others since him have followed. In our de-

scription we shall begin with the more simple, then proceed to the more complicated operations.

Before we proceed, it will be necessary to say how parts separated from each other become united. When a wound is made in any part of the body, from the divided vessels immediately issues forth some blood, which soon coagulates, and this coagulum adheres to the surface of the wound. If the two divided surfaces are brought into contact union will take place between the two, from adhesions of the coagulable lymph to them; however, not sufficient to hold the parts together, unless it is assisted by some artificial means. After having remained so for some time, it will become gradually vascular, so as to produce a communication of vessels between both sides. This is called union by the first intention, which in most cases is generally advised to be aimed at in most wounds. But very often a surgeon is not applied to until all hæmorrhage has ceased, and at a time when the blood which had been effused on the surface has been separated from the part, so as to leave no coagulum. When this is the case, union may still be attempted by the former means, because the extremities of the divided vessels are pouring forth serum and coagulable lymph, which last coagulates with greater firmness than the blood which proceeded from the recent divided vessels. The parts being held together for the purpose till the coagulable lymph becomes vascular, will produce union equally firm and as perfect as in the first instance. This is still considered as union by the first intention, as it makes very little difference in the union. When the vessels have entirely ceased bleeding, and the coagulum has remained some time exposed, it will be better to sponge it away, and bring the parts in contact, leaving them to unite by the coagulable lymph thrown forth afterwards. Sometimes surgical assistance is not called for till the inflammation is abated, till the union by coagulable lymph is lost, and the wound is throwing forth pus, in which case any attempt at union would be ineffectual. Suppurative surfaces will not unite; if the parts, then, are brought so perfectly in contact as to prevent the pus from escaping, it will form a cavity whereby the parts will be rather enlarged, than union facilitated. We must wait for the formation of granulations, then the surfaces may be brought in contact so far as is admitted of without confining the pus within the wound. However, in these cases, where there are such granulations, and a cicatrix is the consequence, the deformity is not so great as might be expected, as there is a power in the gra-

nulations and cicatrix itself to contract. Under these three different modes of union, either by recent blood, coagulable lymph, or by granulations, wounds are frequently united, but the two former are the most to be wished.

There are several circumstances which are unfavourable for union, even where assistance is called for immediately after an accident; as where there is any extraneous body within the wound, as glass, &c.; for though the parts may be brought in contact, and a temporary union produced, in a short time the extraneous body would produce irritation, inflammation, and suppuration, and give occasion to open the wound again, which will be much larger than if it had been left open. If you have any reason to suppose there is a foreign body, you should examine, which is always best done with your finger, if the wound will admit. The same is applicable in almost all gun-shot wounds, in most instances of which there is some extraneous body lodged, as the ball, and perhaps some of the clothes of the patient; in such cases, bringing the parts together will only occasion larger suppurations. These ought to be removed, if it can be done safely and conveniently. If you cannot come at the extraneous body, it is better to leave it to nature, for we find that although gun-shot wounds are often kept open for months, sometimes years, owing to such extraneous substances, nature is gradually attempting their removal. Sometimes they are open through life without inconvenience. Another objection to the union of parts is, where they are considerably contused; union cannot be effected, for these parts being rendered dead by the lacerated state they are in, they are to be considered as extraneous bodies, which makes union here highly improper; on which account gun-shot wounds, independent of any extraneous bodies lodged within, as the wadding of the gun or the patient's clothes, are deemed unfavourable for union. Union is also objected to, where poison has been inserted by the bites of venomous animals, which is not so much the case in this country, though very frequent in hot climates. At the time of the bite or poison being otherwise inserted in the parts, we should attempt to clean out the wound, and remove as much of the poison as possible, leaving the parts separated. The only instance in this country where a bite is attended with any danger, is that from a mad dog; here the part ought to be entirely removed, either by caustic or incision, rather than union effected: however, such a wound may be received on so unfavourable a

part that an operation cannot be performed, as through the cheek or eyelid; of which last I have seen an instance in a girl. The wound was very troublesome, and, after being six weeks in the hospital, she was seized with the symptoms of hydrophobia, and expired in about forty-eight hours. In such cases you may very safely wash the surfaces of the wound with caustic alkali; which, if carefully done, will in all probability remove the poisonous matter inserted, washing it off almost immediately afterwards. The removal may be adopted some time after the wound has been received, probably not only days, but even, with safety to the patient, some weeks after; for there is reason to believe that the absorption of the virulent matter does not take place for several weeks, seldom less than three weeks, and often not under several months: it usually occurs between three and six weeks. The wound will apparently heal up favourably, but some time after the accident the patient complains of a pain, with numbness in the part. This part inflames, and in some instances has ulcerated again. Soon after the pain has taken place the patient is affected with hydrophobia. It is the same with other poisonous matters, as the venereal and variolous, where the absorption is known from the pain in the neighbouring parts. The saliva of a mad dog remains for some time dormant in the part. It seems as if it lay for a length of time unchanged, and then began to stimulate the part. As this seems to be probable, the part being removed any time before the absorption will prevent the symptoms. Where we have an opportunity of removing the part, it should be done as speedily as possible.

In lacerated wounds, union by the first intention may be attempted: they may, I am fully convinced, be safely brought in contact with each other; for where there is laceration there is not always that degree of contusion by which sloughs are formed, for if parts have not lost their living power, union will often be effected. Of this we have frequent instances of the scalp forming a large flap, which, being brought on to the surface from which it had been before separated, and the edges of the wound kept in contact, will be all united in a few days. A needle is a dangerous weapon, as large blood-vessels, tendons, &c. may be wounded, and the latter included in the ligature; hence the action of the muscle is impeded or destroyed.

The sutures now described by modern authors are only four—the *interrupted*, the *quilted*, the *uninterrupted*, and the *twisted*.

The interrupted suture is most commonly used, and is applicable in the greater number

of cases; it is so called from its being usual to divide the thread every time the needle is passed. We use a crooked needle, with a single thread (several threads forming one waxed into a flat form); the broader the surface the easier to the patient, and not so soon producing ulceration in the part*, it therefore holds them better in contact. The size of the needle should be proportioned to the size of the wound. Sutures are used much less by the modern surgeons than they were by the ancients, for it is found in many cases that by placing the limb in a proper position, wounds may often be united by adhesive plaster and compresses. There are parts in the body which would not be properly supported except by these means — as the lips, where the muscles are very strong; the same with the eyelid, if slit from the edge upwards. In such cases, except by ligature, it would be difficult to keep the parts in contact, which I have attempted ineffectually also in the tongue.

We take a needle of a convenient size, and (except in some particular instances) carry it completely to the bottom, to bring the interior surfaces into contact. The distance of the ligatures should be in proportion to the depth of the wound; the distance from the edge should be half of the depth, bringing out the needle at the same distance on the opposite side, cutting off the ligature of sufficient length to tie over the wound in a slip knot. We may begin either in the middle, or at one end: if we use three ligatures we may as well begin at the middle; if more, at one end, gradually proceeding to the other. The distance from each other may be about an inch — sometimes less. The division of a lip of two inches in length would require two or three ligatures to keep the parts in contact. When a wound is very deep, it might be difficult to cause a single thread to pass it to the bottom of the wound, and bring it out at the opposite side. Where this is the case, it would be better to take a ligature with a needle at each end, beginning from the inside of the wound, by which means you would have the ligature in the same way, only passed at twice. When all the ligatures have been passed, having removed every extraneous matter, the edges should be brought in contact, and held there by the assistant while they are tied. Some advise laying lint or plaster under the ligature, to prevent excoriation; however if the ligatures are of a proper breadth, that is unnecessary. The knots should be made on one side of the wound, if over it they produce irri-

tation and pain; a slip knot will be most convenient, so that if much tension comes on, the ligature may be slackened without cutting it. It may be covered over with a bit of lint and common adhesive plaster, to give further support to the parts. In a few days tolerable union will be produced; and as soon as we have reason to believe the surfaces of the wound to be united to each other, as in four or five days at most, the ligatures should be removed, which being done, the parts may be supported with sticking-plaster a few days longer, when union will be quite completed.

The quilled or bougie suture, so called from quills or bougies being used to make it; also peg or loop suture, from the ligature being looped. Mr. Sharpe observes that it is never of any use; that the interrupted is superior to it in all cases; however I think there are some few instances in which this suture is preferable, as where you want to bring a wound in contact which exposes a large cavity, as that of the abdomen. This is done in the Cæsarean operation, rarely performed in this country, where it is considered as not justifiable, if the child can be delivered by any possible means, even by pieces; though in some countries, as France, the mother's life is hazarded more frequently for that of the child. We are sometimes under the necessity of performing it. It consists in making an opening into the cavity of the abdomen to open the uterus. The part for this opening may be on either side, or in the middle. The French surgeons, who perform this operation oftener than we do, generally make the incision on one side, on the *linea semilunaris*, and they prefer the opposite side to that to which the uterus leans, as it is supposed that this inclination to one or the other side depends on the situation of the placenta, and the placenta is a considerable impediment to the performance of the operation from its increased thickness, and numerous vessels which we would wish to avoid. I believe the uterus does incline to the side on which the placenta is situated, but that is not constant; and from the situation of the epigastric artery, I think, on the whole, the incision made on the *linea alba* would be preferable, where you would have an equal opportunity of avoiding the placenta*. It may begin directly below the navel, and be carried five or six inches downwards towards the pubes, the incision being carefully carried quite through the abdominal parietes; next

* Three cases have been lately recorded of the Cæsarean operation having been performed on the continent. Two by Dr. Götsche, one being successful; the third was by M. Aikens, and was also successful. In all these instances the incision was made through the *linea alba*. — C.

* The general opinion, at the present day, is that small round ligatures are better than broad flat ones. — C.

an incision is to be made through the uterus of sufficient length to bring out the child. I once performed this operation on a woman who had just died of apoplexy, where the child shewed some small signs of life. After the child is extracted, all that is to be done is to bring the edges of the wound in contact. The quilled suture consists in carrying a double ligature in the same manner as the interrupted, about half an inch distant from the sides of the wound only, through the integuments and cellular membrane, being careful not to include the peritoneum, which would certainly excite inflammation of the parts. Having passed the ligature through once I make a loop, passing the second about an inch from the first, leaving a loop, I then pass a piece of bougie through each of them; separating the double ligatures on the opposite side, between which also a piece of bougie being laid, is included by slip knots. From the manner in which the sutures are made here, we have a broader surface for pressure than in the interrupted suture. The bougie makes equal pressure throughout the whole length of the suture; in the former the pressure is only where the ligatures are situated. This suture has one inconvenience attending it; though it brings the whole surface of the wound into contact, it does not close the outer lips as the interrupted suture, but does this only in an inconsiderable degree; when, however, the cellular membrane is brought in contact, there is no doubt of perfect union being effected. In deep-seated wounds it will be unfavourable, as it will not bring the outer surfaces in contact. It might be applicable to a large joint involving the capsular ligament: there it requires a large surface to be pressed on, and the needle need not be passed to the bottom of the wound, in which case the quilled suture would be better than the interrupted.

The uninterrupted (from the ligature being carried from one end of the wound to the other without dividing it), called, also, the Glover's suture, is never used now on the living subject*, only in sewing up dead bodies. A straight needle with a single ligature is passed, beginning at one end from the inside outward, then back again on the opposite side, always carrying the needle to the inner side and bringing it out at the opposite, at small distances from each other, which makes it appear neater; towards the end the needle should be passed through, forming a kind of knot, and if the needle is passed under the integuments, neither the end nor be-

ginning of the ligature is seen. It has been sometimes used in the living subject, as in the face, but is usually attended with considerable pain and much deformity afterwards.

Authors, when they speak of sutures, speak of an operation called *gastrographie*, applied to the sewing up of the intestines; this, however, is very rarely necessary; it is only requisite in those cases where a penetrating wound is made into the cavity of the abdomen from which the intestines have protruded, one of which has been wounded, as might be done with the broad sword in engagements between cavalry. The piece of intestine should be sewed up, as may very conveniently be done by the uninterrupted suture passing from without inwards, instead of from within outwards, over the intestine each time, by which the ligature is every time bent over the edges of the wound. Having gone through the whole length, the ends of the ligature should be gradually twisted together. When the aperture of the intestine is thus closed, it should be replaced into the cavity of the abdomen. It might protrude from so small a wound as to be with difficulty returnable. That portion, therefore, which is sewed up should be last returned, and placed near the wound, leaving the ligatures hanging out; then the edges of the outer wound should be brought in contact close upon the ligature, that they may unite in every part except where the ligature hangs out. These ligatures should be left in for some days: when the colicky sensations of the patient indicate that union has in some degree taken place, they should be untwisted and carefully withdrawn, which will only leave the small apertures through which they passed. The patient should be kept on low diet; the ligatures should be well waxed, that they may slip through the intestines with greater ease. Le Dran has mentioned another kind of suture for this purpose, to be made with three needles and three ligatures, more or less, according to the length of the wound. The edges of the wound are to be brought in contact, and the needles passed from side to side, each of the ligatures to be twisted separately, and the whole twisted together, leaving it to hang out at the wound. When union is supposed to be effected, they are to be untwisted and withdrawn one after the other. This but very rarely occurs: even among the cavalry, where it would be more likely to happen, there have been very few instances of the operation having been performed*.

* Mr. Lawrence relates a case in which it was used with advantage in an extensive wound of the abdomen, caused by the tusk of a boar.—C.

* Mr. Lawrence, in his excellent work on Hernia, mentions five cases in which sutures have been used in wounds of the intestines with perfectly successful results.—C.

If it should, the success would be very doubtful; for when you are under the necessity of having ligatures situated within the cavity of the abdomen, they will be liable to produce inflammation of the intestines and peritoneum, which would most likely prove fatal.

We also find authors speaking of sutures of tendons. As ancient surgeons supposed tendons incapable of uniting by themselves, it was directed that they should be exposed, and their extremities brought in contact. We now find the tendon is a part which will unite as perfectly as any other, though not so speedily as more vascular structures, therefore in such cases we have only to attend to the position of the limb, that the extremities of the tendon may be brought as perfectly in contact as possible. Here, too, great rest is rather unfavourable than otherwise, as in divisions of the tendo Achillis, where it would be better to direct the patient to walk about after the inflammation has subsided; the very attempt at muscular action will produce a firmer union than otherwise would have happened. As the tendons become longer by being thus separated, the muscles become shorter, and therefore lose their extent of action; hence we should keep the extremities of tendons as near as possible.

CLINICAL LECTURE

ON

DISEASES OF THE HIP-JOINT,

Delivered at St. George's Hospital,

BY SIR BENJAMIN C. BRODIE, BART.

LECTURE I.

THERE are several cases at present in the hospital of diseased joints, and among these some of disease of the hip; and I do not know that I can offer any subject to your consideration better than this. It is one of great interest, and it is very important that you should understand it as far as the actual state of our knowledge will enable you to do so.

I remember the time when the question, on looking at one of these patients, would have been, whether there were or were not a diseased hip, and the surgeon decided, according to the best of his ability, in the negative or in the affirmative. It was just a case of diseased hip, or it was not, and there was no further attempt at diagnosis. But you know that the hip-joint is composed of a great variety of textures, and that diseases of it must arise from various causes. It would be very remarkable if the hip-joint differed from all the other

organs of the body, and was subject to only one kind of malady. You cannot for an instant hesitate to believe that there must be a variety of diseases of the hip, the difference between them depending partly on the organization of the part in which the disease began, partly on the patient's constitution, and on the external causes by which that constitution has been influenced.

In my treatise on the "Diseases of the Joints," I have given an elaborate history of the diseases to which this and other joints are liable, and I have detailed many cases, and described many dissections, from which I thought I was justified in deducing that history. But in the present lecture I do not propose to pursue the course which I have followed in my treatise. My observations will be confined to the hip joint only. I shall probably refer to other joints sometimes, but it will be only with the view of illustrating what happens in the hip. It will be my object to bring before you at once the different diseases to which the hip is liable, and the symptoms by which they are to be distinguished in the living body. Perhaps by pursuing this course I shall make the subject more easily comprehended by you than it would be if you were simply to read my treatise. At any rate, this mode of proceeding will enable you to understand the observations which I published, when you read them, better than you would understand them otherwise.

Inflammation of the Synovial Membrane.

There is no disease of the joints more common than inflammation of the synovial membrane. The hip is liable to this disease, but it must be acknowledged that it is not liable to it in the same degree with some of the other articulations. You will understand how this may be explained when I tell you that inflammation of the synovial membrane, in a large proportion of cases, may be traced to exposure to damp, or cold and vicissitudes of temperature. The hip is warmly clothed by numerous muscles; an immense mass of flesh lies over it; and thus it is protected from one of the causes which produces inflammation of the synovial membrane, much more than the knee, the wrist, the ankle, and the other joints that are superficially situated.

I conceive that the proper course for you to pursue, if you would study the pathology of any part of the body, is this: be not satisfied with examining the morbid appearances in the last stage of the disease, when all the parts are confounded, as it were, together in one diseased mass—when the disease has extended from the structure primarily affected to the other

parts—and when you cannot, therefore, say where it originated, and what it was in the beginning. Be on the look out for the opportunities which must occasionally occur of examining the morbid appearances, where the patient has died from some accidental cause in an early stage of his complaint; this, I say, is the way in which the pathology of any part of the body (that is, so far as morbid anatomy is concerned) should be studied; and it was in this way that I have always endeavoured to study the diseases of the joints.

I have had very scanty opportunities of examining the morbid appearances presented by inflammation of the synovial membrane of the hip in its earliest stages; but this deficiency has been compensated by the abundant opportunities which I have had of examining the same thing in other articulations, so that I have no doubt that I can tell you very accurately what the morbid appearances would be in the hip if you could see them.

In slight cases, then, of inflammation of the synovial membrane, you find a few more vessels than usual injected with red blood ramifying over the inner surface of the membrane, and the joint contains a larger quantity of synovia than under ordinary circumstances. The synovia, in the cases to which I now refer, does not differ from healthy synovia in any of its sensible qualities. But when inflammation of the synovial membrane runs high, you will find great increased vascularity of the whole of its texture; the red vessels being as numerous as those of the conjunctiva of the eye in a severe ophthalmia: and now the joint contains fluid of another character; not synovia, but a turbid serum. Not unfrequently there are small shreds of coagulated lymph floating in the serum, or broad flakes of lymph lining the synovial membrane in different parts. In protracted cases the synovial membrane is thickened, and you will see in this preparation a sort of pendulous processes, projecting from it into the articular cavity, like what is called chemosis in the eyelid.

In a more advanced stage of the disease, the morbid appearances are not confined to the synovial membrane; the cartilage is found to be thinner in certain places, or totally destroyed by ulceration. In this drawing [presenting it] you see the incipient process of this ulceration; and in these others it is in its more advanced stages. As the cartilage becomes completely absorbed, so a carious surface of the bone beneath is necessarily exposed.

I have said that inflammation of the synovial membrane terminates in effusion of lymph and serum, but it sometimes terminates in suppuration; the surface of the sy-

novial membrane secreting pus in the same way as pus is secreted by the surface of a mucous, and occasionally of a serous, membrane. The joint, when under these circumstances, becomes one large abscess, and if a free artificial opening be not made at an early period, the matter makes its way out by ulceration, through the synovial membrane and ligaments, burrowing among the muscles in the neighbourhood, and forming sinuses. In these cases of suppurative inflammation, the cartilage in the first instance is unaffected, but that in contact with the pus soon begins to ulcerate, and the ulceration of the cartilage, of course, is followed by ulceration or caries of the bones. Here the suppuration is the immediate result of the inflammation of the synovial membrane, and the ulceration of the cartilage and bones is altogether secondary. But then there are other cases where the cartilage begins to ulcerate without pus having been secreted by the synovial membrane, and in which suppuration at last takes place, being not the cause but the consequence of ulceration of the harder textures.

Such is a brief history of the pathological changes produced by inflammation of the synovial membrane in joints generally, and of course in the hip-joint among the rest. I shall next speak to you more particularly of the symptoms of the disease as it affects the hip.

In the first place, then, inflammation of the synovial membrane of the hip is a disease that comes on suddenly, and in the course of two, three, or four days it is commonly at its height. You must remember this circumstance, and contrast it with what I shall tell you afterwards of the early symptoms of other diseases of the hip. Then, in the course of a few days more, under proper treatment, the pain becomes less severe: and now observe the kind and character of the pain. The patient complains of every attempt to move the limb. The hip-joint feels as if it were stiff, and the pain is referred, not so much to the hip itself, as it is to the inside of the thigh and groin; nearly to the same parts as in cases of fracture of the neck of the femur. There is not at this period a wasting, and sometimes there is even a perceptible fullness of the nates. If you press on the condyles of the femur, and squeeze the head of the bone into the socket of the acetabulum, the patient does not complain; nor does he complain if you press on the great trochanter; but if you take the limb and move it backwards and forwards, or if you take hold of the knee and pull it as if you were trying to pull the head of the thigh-bone out of the acetabulum, then pain is felt.

You have heard of dislocation of the hip-joint from disease, and I shall explain to you one kind of dislocation from this cause hereafter. I shall speak at present of dislocation from disease only as it occurs in cases of inflammation of the synovial membrane. I have seen several instances in which dislocation took place under these circumstances, and I conclude that the following is the proper explanation of it:—The cartilage begins to ulcerate, and generally at that part at which the ligaments are inserted. The ulceration extends to one extremity of the round ligament. The acetabulum is filled with lymph and synovia, and the capsular ligament is thereby much distended. There is then, of course, a force operating, which tends to push the head of the bone out of the socket in which it is contained. The round ligament gives way partly from being overstrained and partly from ulceration, and there is nothing to hinder the head of the bone from being drawn up on the dorsum of the ilium. In the particular cases to which I now allude, according to my experience the dislocation is always upwards and outwards, and we see this indicated by the usual signs. The thigh is bent forwards, the toes are turned inward, and the head of the bone may be distinguished lying on the dorsum of the ilium. Before such a dislocation can be effected, the capsular ligament must have been kept for a longer or shorter time in a state of excessive tension; and it will not be difficult for you to understand how much the patient must have suffered in consequence. You know what suffering there is in inflammation and effusion under any unyielding texture; under a fascia, for example, or even under the thick hard cuticle of the thumb or foot. The patient suffers more from tension when the hip-joint is distended with synovia, or serum, or pus, than when the same thing happens to any of the other articulations. And for this plain reason: the capsular ligament surrounds the synovial membrane every where in the hip-joint, which is not the case in most others. In the knee, for instance, when the synovial membrane is distended, the fluid covered by the membrane usually slides up on the fore part of the thigh, under the muscles. Not only great local suffering, but great constitutional disturbance, is usually the consequence of this distended state of the capsule of the hip; severe fever, attended in some instances with a determination of blood to the head, and delirium. I have known such a case as I am about to mention occur two or three times. A girl was seized with an attack of what was supposed at first to be rheu-

matic fever. In the course of two or three days the fever was excessive. She lay in a state of delirium for several days, and she seemed as it were to supersede the local symptoms which existed in the first instance. She nearly died, but by and by things took a favourable turn, and she recovered. After her recovery, her friends looked to the limb, and to their surprise found it very much distorted. Mr. Earle and myself saw the girl under these circumstances, and we found that the head of the bone was lodged on the dorsum of the ilium. In some cases of this kind when the head of the thigh-bone is pushed out of the socket of the acetabulum, the serous fluid which has been collected within the cavity of the capsular ligament makes its way through an ulcerated opening of it into the cellular membrane external to the joint, forming a tumor under the glutei muscles. This tumor evidently fluctuates, and you might suppose it to be an abscess, but take care not to arrive too hastily at this conclusion. It may, it is true, be a collection of pus which cannot be absorbed; but it may, on the other hand, be a collection of serum and lymph, which may be absorbed. The grooved exploring needle (which you see so frequently used with advantage in this hospital) may be usefully employed in this case. Puncture the tumor with it. A little of the fluid will probably escape along the groove, and if you find that it is really purulent, you may then introduce a lancet, and make a free opening; but if it be serum you will take care to go no farther. It is doubtful whether pus is ever absorbed. If this ever happens, it certainly is a rare occurrence; but an effusion of serum becomes absorbed ultimately. If you find the fluid to be serous, you have nothing to do but to leave the patient quiet, and wait for the time when absorption will have taken place. If you open a cavity containing serous fluid with a lancet, in all probability you induce suppuration, and thus make an abscess where there was no abscess before.

Such, then, are the principal circumstances respecting the pathology and the symptoms of inflammation of the synovial membrane of the hip: I shall speak of the treatment in another lecture. But before we go farther I should like to call your attention to a preparation which is now on the table, taken from a patient who died lately in this hospital. I think it not improbable, though we do not know enough of the history of the case to speak with certainty—for we did not see the disease till it was far advanced—that here the original disease was inflammation of the synovial membrane. The cartilage is exten-

sively ulcerated, the synovial membrane is rather (not a great deal) thickened, but the circumstance which leads me to suspect that the original disease may have been inflammation of the synovial membrane, is this, that the joint was filled with a number of small granular bodies, composed of coagulated lymph, and I know that in other cases these bodies are the result of inflammation of the synovial membrane. You find them sometimes in joints, but more frequently in the synovial membranes which constitute the bursæ, and sheathe the tendons. These granular bodies, after a considerable time, assume an appearance like that of small melon seeds, becoming flat and smooth, and of an oval figure. The joint in this instance contained a great quantity of these bodies, and they had caused the head of the bone to be partially pushed out of the socket. There is a groove formed in the head of the bone, where it had rested upon the edge of the acetabulum. If this patient had lived some time longer, the bone would have completely escaped out of the socket, and become lodged on the dorsum of the ilium, so that there would have been a complete dislocation. As it was, the dislocation was incomplete, or what they call a subluxation.

The chronic diseases of the hip more frequently have their origin in the harder textures than in the synovial membrane. It is very common to call all diseases of the hip joint scrofulous, but it is also very common to call any disease scrofulous. The fact is, that in most cases diseases of the joints are not scrofulous, not particularly connected with a scrofulous diathesis; but there is one disease of the joint which is especially of this description, and of that I shall speak to you next.

Scrofulous disease of the hip.—This disease has its origin in the bony structures. It occurs most frequently in children, and very rarely after 25 years of age. We meet with it especially in those children who have a fair complexion, light hair, blue eyes, and wide pupils; and who are delicate and precocious.

If you examine the morbid appearances in the early stage of the disease, you find the synovial membrane, the ligaments, and the cartilages, quite sound, but there is a peculiar alteration in the articulating extremities of the bones. You can even cut them with a scalpel without turning its edge, there being in them less earthy matter than natural. The cancellous structure of the bone is unnaturally vascular, and a small quantity of serous fluid is to be found in the cancelli. But in a more advanced stage of the disease the bones become still softer, so that you may crush them by pinching them with the fingers;

and, now, the cancellous structure, instead of being more vascular than natural, is less vascular, and, instead of a serous fluid, you find a yellow cheesy matter in the cancelli. The vascularity of the bone goes on diminishing, and in some parts of it the vessels become so much obliterated that the bone dies, and becomes an exfoliation. Here is a section [presenting it] of the femur and tibia, where you will see both stages of the disease. Here is another [exhibiting it], shewing scrofulous disease of the bones as plainly as it can be seen in a preparation. If these dried preparations [exhibiting them] were out of the bottles, you would be struck with the lightness of the bones, from want of earthy matter. Here is a drawing [exhibiting it] from a private patient who had disease in one hip-joint. On examining the opposite joint, in which no disease had been suspected, there was the appearance of the head of the femur which you see in this other drawing, occasioned by increased vascularity in some parts, and a deposition of cheesy matter in others. The surface of the bone next to the cartilage being diseased, you may well suppose that the cartilage itself will become diseased afterwards: and so in fact it does. The cartilage loses its very firm adhesion to the bone, and you may peel it off, and as you do so, a red vascular surface of the bone is to be observed underneath. The surface of the cartilage where you have peeled it off is a little rough. Here is a specimen [exhibiting it] illustrating what I now mention. The cartilage then begins to ulcerate. How is it that the ulceration of the cartilage takes place in these cases? The ulceration begins on that surface which is towards the bone; and as it is thus, as it were, eaten away, the space formed between the cartilage and the bone is filled up by coagulated lymph, which becomes organized. The ulceration goes on, getting deeper and deeper, till it penetrates through the cartilage, making at first a small opening, through which a probe may be passed until it comes in contact with the bone. The ulceration by degrees extends in every direction, and ultimately the cartilage becomes every where destroyed. Here is a drawing of the other hip-joint of the patient, to which I referred just now. There is a section of the head of the femur, and you see a yellow cheesy deposit within, while the cartilage has completely disappeared from the surface. As the disease makes still further progress, suppuration becomes established in the joint; but the cartilage in these, as in other cases, often ulcerates to a considerable extent without the formation of abscess. It was shewn by

Mr. Hunter that suppuration and ulceration are not necessarily connected; at least that you may have suppuration of the mucous and other membranes without their being ulcerated; and there are numerous facts connected with the pathology of the joints which establish the converse of this, shewing that ulceration may take place without the formation of pus.

I will now state the symptoms which this serofulous disease produces in the hip. The most remarkable thing is the small quantity of pain which it for a long time produces. Indeed, the serofulous disease of the bones when the cartilages are unaffected may exist without any pain whatever; and over and over again I have examined cases where children died affected with serofulous disease to a great extent in one hip-joint, but where they have never complained of pain in the other hip, although the *post mortem* examination proved that to have been affected also. Even when the cartilages begin to ulcerate there is at first only a trifling degree of pain. The disease is, indeed, most insidious in its origin. I was called to see a child, many years ago, in consequence of the parents having observed him to limp in walking for some time previously. That was all: he had never complained of pain, nor were there any other symptoms. I examined the joint, and found that I could push the head of the bone into the socket of the acetabulum, and move the limb in any direction without producing the smallest uneasiness. I took a great deal of pains to make out the case, and told the parents that if we did commit an error it was better that we should make it on the safe side, and I therefore advised them to lay the child up, as if the hip was diseased, although I was by no means certain that it was so. It was well that I did give that advice, for the next account which I had, some months afterwards, was, that there was a considerable abscess in the hip. I believe the poor child ultimately died. I have seen similar cases since, in which children have been brought to me in consequence of their limping, but without pain, and it has proved to be this serofulous disease of the hip-joint. The disease may then go on for weeks and months, the child having some pain, but not a great deal, and very often when the relations are careless the disease is quite unobserved for a long time. But by and by the child begins to make greater complaints, sometimes of pain in the hip, but more frequently of pain in the knee, and you observe him putting its hand to the joint last mentioned. Then the pain becomes greater, but I suspect that in these cases the pain is never very considerable till an abscess is

formed in the joint, and then certainly the child suffers enough. At this period it cannot bear to be moved, it lies in one position in bed, and generally twists himself round into a very awkward posture, making one hip very much bulge out, and the knees crossing each other, so that there is a great deal of deformity. The child screams from pain in the day, but he suffers chiefly at night: he wakes out of his sleep screaming, and complaining of frightful dreams. Bad dreams in children, and, I believe, in grown-up persons, generally depend upon something wrong in the physical system. That which would be pain in the knee from the diseased joint if the child were awake, becomes a frightful dream if he be asleep. You must not wonder at this when you consider that even acid in the stomach is a frequent cause of disagreeable dreams in an adult. By and by an abscess presents itself in one place or another. Sometimes it makes its way on the inside of the thigh; sometimes backwards, shewing itself behind the little trochanter; sometimes outside under the nates; and sometimes it penetrates by ulceration through the bottom of the acetabulum, into the cavity of the pelvis. In the latter case it not unfrequently bursts into the vagina or rectum; and I do not see why, in some instances, the matter should not make its way into the urinary bladder, though I do not recollect having met with an example of this myself.

When an abscess presents itself externally from this disease, there is invariably another change in the condition of the limb. It becomes shortened, and this occurs in two different ways. If the head and neck of the bone be destroyed, and especially if the margin of the acetabulum be destroyed also, it is no matter of wonder that the muscles should pull up the thigh bone, and that the limb should be shortened. Here is a drawing of the head of the thigh bone where there is only a small part of the neck left, and where a very little action of the muscles would pull the thigh bone out of the socket and lodge the remains of the neck upon the *dorsum* of the ilium. In these cases the limb is shortened just in the same way in which it would be shortened in a case of fracture of the neck of the femur. The toes, if left to themselves, turn outward, and the thigh may remain in a line with the trunk. But at other times the shortening of the limb takes place in another way. The cavity of the acetabulum is filled up by lymph or pus, or by lymph and pus altogether, the capsular ligament of the joint in consequence is dilated, the patient having undergone a great deal of suffering from the tense state of the capsule pre-

vionsly. Then the round ligament is destroyed by the ulceration which has already consumed the cartilage. The head of the femur is pushed from the joint until it passes beyond the margin of the acetabulum, and then the muscles pull it upwards, and lodge it on the dorsum of the ilium. Sometimes, when the head of the femur is dislocated, it will be nearly entire; in other cases it is partly absorbed. The dislocation is generally in the same direction, and here as in those other cases, in which dislocation arises as a consequence of inflammation of the synovial membrane; the dislocation being upwards and outwards, the limb is much shortened, and the toes are turned inward. There is one circumstance which favours the escape of the head of the femur from the socket of the acetabulum, and also favours the escape of the remains of the neck wherever the head has been destroyed; and that is, the position in which the child generally lies if left to himself, with his knee bent inwards, so as to cross the sound limb. This cannot be done without making the trochanter project on the side of the disease, and this favours the escape of the head of the bone.

There are a few cases in which dislocation takes place in another direction. I had a patient under my care who has now recovered, but who had, a few years ago, disease in the hip-joint, and there the head of the femur has been dislocated forwards. It may be felt upon the ramus of the pubes, the great trochanter being, of course, placed farther back than natural, and the toes being turned outward. The child is better off than when the dislocation is upwards and outwards. There is, it is true, a little shortening of the limb, and the child has the toes turned out, but she can walk very well nevertheless.

I need not tell you that these cases of the hip-joint, if they proceed to the last stage, are very dangerous. But why should the disease be dangerous? The hip-joint is not a vital organ. The fact is, that disease of the hip-joint is very rarely the immediate cause of death; but when an abscess has burst externally, discharging matter, and has continued to do so for a long time—when the patient has been long exhausted by suffering and night perspirations, disease takes place in the thoracic and abdominal viscera. Such circumstances are always favourable in bad constitutions to the production of disease, especially in the lungs and mesenteric glands. In like manner serofulous persons may become phthisical when the constitution has been weakened by ague, by a course of mercury, by the venereal disease, by scarlet fever, or measles, or any thing else.

I mentioned that a great aggravation of pain takes place when suppuration is established in the joint. The escape of the head or neck of the thigh-bone from the acetabulum tends not at all to diminish the patient's sufferings, but rather to increase them. When this has taken place the patient of course is relieved so far as the tension is concerned; but he now suffers from another cause. The head of the thigh-bone in some cases, and the ulcerated neck of the femur in other cases, coming in contact with the soft parts in the vicinity of the joint, keeps these parts in a state of irritation, and every attempt to remove the limb, even the slightest, is a source of torment.

ON THE SIGNS OF PREGNANCY.

To the Editor of the Medical Gazette.

SIR,

IF you think that the following case of obscure pregnancy, where the pregnant uterus was mistaken for a diseased ovary, is likely to interest any portion of your readers, its insertion will oblige

Yours respectfully,

JOHN ROBERTON.

Manchester,
Sept. 10th, 1838.

On the 2nd of November, 1837, I was requested to visit, for the first time, Mrs. —, suffering from a feverish cold. She was about 22 or 23 years of age, of rather delicate health, and ten months married. Was informed that she supposed herself six or seven months gone in pregnancy, but that she was rather in doubt. The next day (3rd.) on inquiring if she had quickened, she replied that she had not, and gave me the following history:—

Had never menstruated regularly; was unwell, for the last time, on the 16th of April, that is, thirty weeks previously; soon after had sickness, particularly in the evening. In the beginning of May, about a fortnight after the disappearing of the catamenia, the breasts began to run, and a copious discharge of a serous kind had continued ever since. At the same time the breasts enlarged and became tender. About the beginning of July was sensible of pain and uneasiness in the belly, above the right groin; and, not long after, detected a swelling or fulness in that situation. From this period the shaking of a coach

caused distressing pain in the part; as did also the act of running up or down stairs, the latter so much as to compel her often to sit down for ease on a step. At times she could with difficulty detect the swelling, but at other times it was prominent, and easy to be felt; says she never was aware of any motion within resembling what is called *quickenings*, nor of movements such as might be attributed to a child. The right foot was slightly œdematous; and when my attendance commenced, there was a sense of pain and numbness in the right limb.

Laying my hand upon the abdomen (Mrs. — being undressed, and in bed) I readily discovered a very firm tumor, of the figure and about the size of a cocoa-nut. It was painful when pressed, and lay obliquely above the right groin, pointing in the direction of the upper and back part of the os ilium, occupying the space between the umbilicus and the anterior superior spine of that bone. It seemed to me to be an enlarged ovary, or a fibrous tumor connected with the uterus,—an impression which led me to say that it was not pregnancy. On examining the nipple, the areola was in colour unchanged, being a pale red; and the follicles, as far as I could perceive, were undeveloped*. The tumor, it may be as well to repeat, lay on the right side of the median line, the umbilicus being a *pit* as much as it is in those who are not pregnant.

In the course of a few days, as Mrs. — continued feverish, and complained of constant and severe pain in the tumor and right limb, particularly in the night, my friend Mr. Wilson, a very experienced practitioner, was called in consultation. Mr. Wilson accordingly made an examination for himself, and reported to the family that the enlargement was not from pregnancy, but what the nature of the tumor was he could not then decide.

Up to this period I had thought the tumor to be fixed, not having observed it shift its situation; but now Mr. Wilson and myself discovered it high in the abdomen, to the right of the umbilicus, and so prominent as to admit of

its being grasped by the hand and moved about: in a minute or two it would subside into its usual situation. This shifting about of the tumor we repeatedly noticed. It was firm to the touch, and painfully tender when pressed or handled otherwise than gently. On making our patient lie on the left side, the tumor fell towards that side, so as to be in part on the left of the median line; but on again turning on the back it settled, as at first, in the right iliac fossa. Complains that it moves about in the night; at which season her sufferings are the greatest. When, as she reports, the feverishness and restlessness are very distressing.

At Mr. Wilson's request I made an obstetric examination. With difficulty I reached the os uteri, for it lay at the left side of the pelvis, as high as the brim, near the left groin. The neck of the womb was full and rounded, rather than projecting.

November 20th.—At this date Mr. Wilson and I were of opinion (which we expressed to the family of our patient) that the tumor was ovarian, probably of the nature of an abscess; for the pain in it was constant, and the nights were feverish and sleepless. Her aspect also was wan and unhealthy, and she frequently vomited her food.

On the 24th of November (that is, on the twenty-second day from the period of my first seeing her), Mrs. — was taken early in the night with unusual pains in the abdomen. When I paid my visit in the course of the following day, I did not suspect them to be uterine. In the evening she, before my arrival (Mr. Wilson being present), gave birth to a fetus, which was shriveled, as if not recently dead, and weighed eleven ounces and one quarter avoirdupois. The after-birth followed. There was no sensible discharge of liquor amnii, as Mr. Wilson informed me.

It deserves remark that at the date of the miscarriage, Mrs. — must have been, according to her own computation, at the commencement of the eighth month of pregnancy; and the fetus have lain, *in utero*, dead three months and upwards.

For several days and nights subsequently to the expulsion of the fetus, the pain and tenderness in the right side of the belly continued with distressing severity. It however gradually, though slowly, left her.

* On the second or third day after the delivery of our patient, I again examined the areola, and thought the colour had now a tinge of yellow, and that a few follicles were enlarged, though, if at all, in a very slight degree.

The watery discharge from the nipples continued for a number of weeks as profuse as ever; so profuse as, in a short time, to soak her dress unless when the nipples were covered with carded cotton or folds of flannel. From first to last its duration was little short of nine months.

These are the chief reasons which induced Mr. Wilson and myself to think that Mrs. —'s symptoms did not indicate pregnancy:—

1st. Her not having quickened, although more than thirty weeks had expired from the last appearance of the menses; and this taken in connexion with the fact of her having experienced, from the age of puberty, habitual irregularity as respects the menstrual function.

2d. The profuse serous discharge from the nipples commencing in about two weeks after the disappearance of the menses.

This is rare at so early a period of pregnancy.* Dr. Montgomery says that when milk is secreted during pregnancy it is not to be regarded as a sign available as a guide in forming an opinion in a doubtful case, because it does not make its appearance "until a period has arrived which presents other modes of judging, less liable to uncertainty."—(See Signs, &c. of Pregnancy, p. 74). In a private communication with which Dr. M. has obligingly favoured me, he states having *recently* attended on a lady, who, in four months after her marriage (probably about three months after impregnation) had "such a copious sero-lactescent secretion from the breasts, that she was obliged to wear folds of cotton inside her dress, to save it from being spoiled by the wet."

3d. The unaltered state of the areola. If there was a change either as respects the colour of the areola or the development of the follicles, we failed, in the first instance, in detecting it. After the expulsion of the fœtus, a knowledge of the fact that there *had been pregnancy*, enabled me to detect, as I thought, a slight change. However, the usual changes in the ordinary degree of distinctness might have existed (probably *did exist*) in the earlier months, and have

disappeared, in a measure, owing to the death of the fœtus *in utero*, which event probably happened about ten weeks previously to my seeing the patient.

The fading away of the changes in the areola, after the death of the fœtus *in utero*, is a circumstance worthy of very particular attention, since in those cases where a blighted fœtus is retained for any considerable time in the womb, it must greatly lessen the *distinctness* of the signs indicating pregnancy. This is pointed out by Dr. Montgomery (and by no previous writer so far as I know), who remarks, that when the usual *changes* in the areola have been established, should the fœtus be blighted, they "soon decline and fade away."—*Signs*, &c. pp. 63 and 96.

4th. The abdominal tumor appearing not in the umbilical region, but above the right groin, in the right half of the abdominal cavity; and, just before the expulsion of the fœtus took place, rising nearly as high as the edge of the ribs; also, the umbilicus being a *pit*.

I find one case recorded by Dr. Montgomery, which has several features resembling the above:—

"Some years ago a married lady, who had menstruated for the last time on the 10th of November, came to Dublin in March, on the 21st of which month a consultation was held to determine whether she was labouring under a disease of the womb or not, as she had been previously assured by her medical attendant that she could not be pregnant, because she had not felt the child, nor had sick stomach, with which she had always been much distressed in former pregnancies. On examination, the writer distinctly felt through the abdominal parietes the limbs of the fœtus *in motion*, as did also Mr. Cusack and Dr. Marsh, and yet the lady herself had no consciousness whatever of any such sensation, nor did she *quicken* till the second week of the following month (April), and was delivered of a healthy baby on the 9th of August. In addition to considerable pelvic pain and irritation of the bladder, with very sedimentous urine, the symptom which had excited the greatest alarm in this lady's case was one which, at the time, I had never met with, but have seen two or three other instances of it since. For about a month previous to her coming to town she was occasionally sensible of

* In rare instances of diseased ovarium the breasts are tender and painful at an early stage. In some cases, likewise, milk is secreted.—*Burns' Midwifery*, 7th edit. p. 127.

pain in the right iliac region, and at the same time a firm tumor could be felt *gathering*, as she expressed it, in the seat of the pain; and both were considered as the effect of disease. During our visit this happened, and I had an opportunity of examining it, and ascertained that it arose from partial spasmodic contraction of some of the uterine fibres about the right cornu, probably having its seat in the orbicular muscle which surrounds the orifice of the fallopian tube. I kept my hand in contact with the hard tumor thus formed until it gradually relaxed and softened down, so as not to be any longer distinguishable from the rest of the uterus, which lay in the right iliac hollow. This had never occurred in any of her former pregnancies, nor did it in any of three subsequent ones.”—*Signs*, &c. p. 77.

This, it will be admitted, is a most interesting case. There was, as in Mrs. —’s case, the pain in the right iliac region, and the firm swelling; but here the resemblance ceases; for the uterine tumor was in such a condition as to allow the limbs of a *living* and *moving* fœtus to be distinctly felt through the abdominal parietes. (See also pages 108 and 109.)

5th. The rounded figure and remarkable firmness of the tumor, unlike the pregnant uterus; its high situation in the abdomen, its shifting about, its tenderness on pressure, and the dull aching pain usually experienced in it.

A case of pregnancy is related by Dr. Montgomery, where “the uterine tumor felt as hard as cartilage, and knotty all over its surface; was very painful, and exquisitely painful and tender to the touch.”—Page 68. Here the tumor was not lateral in position, but situated in the centre and lower part of the abdomen.—See also page 110.

6th. The nightly attacks of fever, the pulse, even during the day, being from 86 to 90; the countenance at the same time being sallow, and expressive of ill health.

7th. The pain and numbness confined to the right limb, with œdema of the right foot.

œdema and varicose veins are oftener found affecting the right than the left limb in the pregnant; but, according to my observation, neither the œdematous swelling nor the enlargement of the veins makes its appearance in the limb,

in a first pregnancy, until the gravid uterus begins sensibly to distend the abdomen. In the above case the numbness felt in the limb, and the slight œdema visible chiefly on the foot, both of which were manifested at a very early period, resembled rather the effects of pressure such as might arise from an enlarged ovary resting behind the groin, than from a pregnant uterus.

8th. The os uteri higher than natural, and thrown to the left side of the brim, as if by a heavy body acting on the fundus uteri, and dragging the uterus towards the right side of the abdomen. The rounded form of the cervix uteri I could not then, nor can I now, explain, since it is probable that the shrivelled fœtus must have lain encysted, so to speak, and pressed together like a round ball in the upper part of the uterine cavity. There was, it is to be remembered, no sensible quantity of liquor amnii.

For the following ingenious explanation of these features of Mrs. —’s case I am indebted to the great kindness of Dr. Montgomery, who, in a private communication, before referred to, thus expresses himself:—“Pregnancy began in the usual way, and went on for four or five months at least; then, from some unhealthy change in the uterus, or in the appendages of the fœtus, the latter was blighted, and of course ceased to grow; the liquor amnii was absorbed, the uterus gradually closing on and compressing the fœtus, so as to force it gradually and *with pain* into the cervix, which, consequently, you found rounded and bulging, rather than projecting, a short time before the expulsion of the fœtus; while the uterus itself was of course hard, and very sensitive, and fever and irritation spread, as a necessary consequence, through the constitution.”

The reader who may take an interest in inquiries of this nature will do well, after considering each particular symptom by itself, to consider the whole *collectively* as the features of one case; for by this method only will he arrive at a just estimate of the difficulties which lay in the way of a correct diagnosis.

That the opinion delivered in this case, proved by the issue to have been erroneous, is open to comments, I am ready to admit. I will leave them, however, to be made by the intelligent

reader at his own leisure; who, while he learns caution by the error, may also, by the unvarnished narrative here presented, learn the great importance of the study of the signs of pregnancy, and the perplexing difficulties with which that study is, in some instances, beset.

DISLOCATION OF THE FEMUR.

To the Editor of the Medical Gazette.

SIR,

THE perusal, within the last few days, of a "Case of Dislocation of the Femur on the Obturator Foramen," communicated by Mr. Skey, in your journal for August 4th, has recalled an instance of the same injury which occurred in this hospital in the year 1834.

As the reduction was effected, as it were, accidentally, with remarkable facility, I have thought that the recording of the circumstance might not be unattended with practical utility in the treatment of this accident. Should you be of the same opinion, you will perhaps allow the following short account to appear in your columns.

I am, sir,

Your obedient servant,

GEORGE BUSK,
Surgeon to the Seaman's
Hospital.

H. M. S. Dreadnought,
Sept. 10, 1838.

Richard Pippen, a seaman, aged 26, stout and very muscular, was admitted in the evening of December 14, 1834, having met with an accident two hours previously. He was standing on the deck of his vessel, in a stooping posture, with his legs wide apart, when he was struck suddenly on the right thigh by the main-boom, which had been carried away.

When laid on his back in bed the thigh was considerably flexed on the pelvis, and extremely abducted; the knee bent, and the foot everted. The prominence of the trochanter was absent, and a hard tumefaction could be felt in the upper and inner part of the thigh, beneath the abductor muscles; but the head of the femur could not be defined. The psoas and iliacus, where passing over the edge of the pelvis,

could be felt much on the stretch; flexion and abduction of the limb were tolerably easy, but extension and adduction impossible. The knee was also extended with great difficulty. When directed to stand upright, the injured limb retained the same position, and the toes touched the ground; the foot being widely separated from, and somewhat in advance of, the other. He did not suffer much pain. There could be no doubt as to the nature of the injury, and the reduction was proceeded with immediately. The man was placed in a hot-bath, and, while in it, bled to approaching syncope, which required the abstraction of twenty ounces of blood. When taken from the bath, half a grain of tartarized antimony was administered, and he was placed on his back on a thin mattress spread upon the deck; two hooks were fixed on either side of him, opposite each other, and about six feet apart. Two bands were applied, in the mode directed in Sir A. Cooper's work on Dislocations—viz. a padded strap was passed round the right side of the pelvis, and the ends fixed to the hook on the left side. Another similar strap was placed round the inner side of the thigh, and as high as possible, pass-posteriorly within the strap which fixed the pelvis. This thigh-strap was connected by the pulleys to the hook on the right side. No means were used for producing extension of the limb. The pulleys were then gently drawn, but the cord very slightly tightened. I then took hold of the foot, with the intention of adducting the limb, at the same time that extension was made by the pulleys; but had hardly commenced doing so when my colleague, Mr. Tuckett, in stepping from the man's head towards his feet, struck slightly with his foot the extended cords of the pulley, and by the sudden yet trifling jerk thus produced, the head of the femur was raised from its position and replaced in the acetabulum with a distinct snap.

The motions of the joint were of course instantly restored. The limb remained for four or five days about half an inch longer than the other, but at the end of ten days the man returned to his duty.

TUMOR INVOLVING CERTAIN NERVES.

To the Editor of the Medical Gazette.

SIR,

If you are of opinion that the points connected with physiology and pathology in the following case, render it worthy of a place in your very valuable publication, I shall be much obliged to you to give it insertion.

I am, sir, your obedient servant,

EDW. SELLECK HARE, M.R.C.S.

House-Surgeon to the Stafford County General Infirmary.

September 11, 1838.

Thomas Willetts, aged 40, married, of an unhealthy complexion, was admitted to the Infirmary, under the care of Dr. Knight, on the 8th of last June. He had been attacked a month before with pain, tingling and numbness along the course of the ulnar nerve of the left arm, which was most severe at the elbow, where there had also been some swelling and redness. There was, besides, pain through the left shoulder, extending across the chest to the opposite side, and upwards to the left eye and teeth of that side; also a sense of pulsation in different parts of the body, and sleepless nights. The tongue was clean, appetite good, no cough, or physical sign of pulmonary disease, and the secretions were all natural.

After a careful examination, the only cause that could be discovered to account for his symptoms was a small tumor, situated in the "inferior triangular space," on the left side of the neck, which it was possible might be producing some pressure on the origins of the nerves going to form the brachial plexus: the pulse at the wrist was equal to that of the other arm. The tumor, however, did not appear to be more than an enlarged gland, and the disease was supposed to be of a serofulous nature.

In addition to the foregoing symptoms, the pupil of the left eye became contracted; and the levator palpebrae ceased to perform its office, the general irritability increased almost to mania, and the bowels became very torpid. In about three weeks after his admission, the pains and distressing sensations appeared to be increased, the pulse had become quicker, there were signs of de-

bility, with numbness and coldness of the lower extremities; also by this time the tumor of the neck had become more extensive, and possessed a remarkable degree of hardness.

On the 20th of July he had almost entirely lost the power of sensation and motion in the lower extremities; and in a day or two afterwards there was a complete retention of urine. The catheter was used for about a week, when the urine again flowed, but without his being conscious of it; but he could partly empty the bladder when he chose, by the pressure of the diaphragm, scarcely, if at all, assisted by the abdominal muscles. On the 25th a slough began to make its appearance over the sacrum, but it occasioned him no pain. On the 12th of August the process of sloughing set in over each trochanter, he having been alternately laid on either side, in order to avoid the ulcer on the back. By this time the tumor of the neck had very much increased in size and prominence; the three ulcers became very extensive, and the suppuration copious; his strength gradually failed till the 26th of August, when trismus came on with paralysis of the muscles of deglutition and expectoration; and he died from suffocation at four o'clock on the following morning.

With respect to the treatment, I may observe that opiates procured him sleep, and relieved the pain without any unpleasant effect, and the eyes became more equally opened, and the pupils more symmetrical when he awoke in the morning. The repetition for a few days of exceedingly small doses of blue pill, which he took with extract of henbane, produced soreness of the gums and the mercurial breath. Leeches and blisters were repeatedly applied over the tumor, but without any effect. When the extract of belladonna was applied, the pupil of the left eye recovered its natural size for a time. Tonics and stimulants agreed, and no doubt prevented his sinking so soon as he otherwise would have done, from the inroads of the disease. For some time, also, his appetite did not fail him, and he took considerable quantities of nutritious food.

Post-mortem inspection.—The examination of the body was begun twenty-eight hours after death: it was now greatly emaciated. There was œdema

to a small extent in the legs and left arm.

The brain and spinal prolongation and their investing membranes were carefully examined, but no disease of any kind was detected. The optic nerves were of the same size and firmness: that portion of the medulla spinalis which swells into the cauda equina was particularly firm; there was little or no fluid in the great cavity of the arachnoid, not a large quantity in the lateral ventricles, and that in the spinal canal inconsiderable.

Dissection of the tumor.—After dissecting back the skin and platysma, from the left side of the neck, the superficial cervical fascia was found to be unusually dead, and the cellular tissue about it infiltrated with serous fluid. It being removed, the tumor presented its irregular surface, and was found to possess the hardness of scirrhus. Some considerable veins passed into its substance, and it extended under the sterno-cleido-mastoideus and trapezius, raising on its surface the omo-hyoid, sterno-hyoid, and thyroid; which, however, were not implicated in the disease. After the removal of these the tumor was seen to extend upwards as far as the origin of the brachial plexus. The carotid artery, internal jugular vein, and pneumo-gastric nerve, passed into its substance; the first remaining pervious, the two last lost and transformed into the diseased structure, as were also the phrenic nerve, and further down the sympathetic, with its lowest cervical ganglion. The jugular vein above the tumor was atrophied, and the pneumo-gastric nerve was œdematous. The scirrhus mass extending under the clavicle, the latter was removed, and the following were its further relations:—The subclavian artery and vein passed into its substance, that portion of the anterior scalenus which separates the artery and vein, and nearly the whole of the muscle, being included in the disease, and undistinguishable. Both the artery and vein were pervious, but the latter was filled with a coagulum of a deep red colour. The tumor extended inwards as far as the trachea and arteria innominata, and downwards behind the left vena innominata and subclavian and carotid arteries, as far as the aorta, impinging upon it at the junction of

its arch with the descending portion. The thoracic duct passed into and was lost in the disease, as also were the recurrent laryngeal nerve, and the veins accompanying the branches of the subclavian artery,—the branches of that artery themselves passing through the tumor without being converted into its nature. The tumor lay upon the brachial plexus, being firmly attached to the spine at the origin of the third and fourth nerves of the plexus, both which were inseparable from it.

Upon cutting into the anterior surface of the scirrhus, watery pus escaped, and the surrounding cellular tissue was œdematous. The carcinomatous mass extended itself in company with the last cervical and first dorsal nerves between the transverse processes, and into the intervertebral foramina as far as to the dura mater, which appeared beginning to be implicated; but the canal was perfect, and the appearance of the theca of the medulla not at all altered. There was no appearance of carcinoma in any other part of the body.

OBSERVATIONS.—The case seems to be interesting as an instance of glandular scirrhus in the male. The connexion of the disease with the distress and paralysis along the course of the ulnar and median nerves is obvious, and is evidence in confirmation of the assertion that these nerves can be traced through the plexus to the last cervical and first dorsal nerve, which I believe Boyer denies. The paralysis of the levator palpebræ, which receives a branch from the third pair; the contraction of the pupil; the pain of the teeth; the distressing sensation across the upper part of the chest; the paraplegia; the sense of pulsation in various parts of the body; and the maniacal disturbance of the mind, cannot, I apprehend, be referred to any *direct* communication between the structural disease and these several affections, but rather they must be regarded as an instance of that remote sympathy which is found to exist between distant parts of the same individual, and is most frequently displayed in persons of a nervous temperament. The œdema of the arm might possibly depend on the existence, during life, of the coagulum found in the subclavian veins; but the swelling of the elbow, which occurred at a much earlier date, could scarcely be supposed to depend on

any impediment to the circulation at that period, and is interesting as shewing how pain and irritation of the nerves of a part, existing only sympathetically with a distant cause, may lead to structural alteration in such part, and is parallel to what occurs in hysterical females, of which I have seen many examples. The stoppage of the thoracic duct without much emaciation, perhaps is parallel to maintenance of "enbonpoint" by hysterical patients, with the most complete anorexia for very long periods. The length of time during which the patient was bed-ridden, and the degree of emaciation and debility, taken together, were not sufficient to account, of themselves, for the sloughs over the sacrum and hip, which probably owed their existence to the paralysis of the nerves of animal life; and the fact tends to demonstrate the influence of this part of the economy over the nutritive functions.

CASE OF VARICOSE VEINS,

TREATED BY MEANS OF THE TWISTED SUTURE.

(Communicated by Sir Jas. Macgrigor, Bart.)

ANDREW ROSS, aged 32, 84th regiment, admitted into hospital on 12th July, 1838, with a large ulcer over the front of the right leg. The skin is unhealthy over the whole of the lower part, from old cicatrices.

This man has served in the West Indies for ten years, and states that for the last five he has been subject to constant ulceration of the leg, and enlargement of the veins, which are now of a considerable size, and in a varicose state, from the groin to the ankle. The diseased branches on the leg are numerous, and very tortuous. Under these circumstances there was no hope of permanently curing the ulceration without first curing the varicose veins. With this view, seven common surgical needles were inserted under the different diseased branches, and the twisted suture applied firmly to compress the sides of the veins. One of the needles was put under the saphena, about the middle of the thigh. Slight inflammation was produced from the needles, ulceration gradually went on, and the needles completely ulcerated through,

and finally came away on the eleventh, thirteenth, and fifteenth days after insertion.

The ulcer on the leg got quite well, and the man was discharged to duty on the 17th August, feeling very comfortable about the leg, and without any enlargement of the saphena vein in the upper part of the thigh and groin left.

A. MELVIN,
Surgeon to the Forces.

Portsmouth,
31st August, 1838.

CASTS OF ANATOMICAL SPECIMENS.

To the Editor of the Medical Gazette.

SIR,

I BEG to forward you, for publication, an account of the process for casting from morbid anatomical specimens, which has lately received the silver medal of the Society of Arts.

The necessary dexterity is so easily acquired, and the expense is so trifling, that many may be induced to make trial of this method of preserving their preparations;—and as these are days in which any, even the smallest discovery in art or science, seems to furnish subject for attack and violent discussion, I would here wish to disavow any originality as to the nature of the composition of which the moulds are made, the undermentioned ingredients in various proportions having been in use amongst modellers and workers in plaster for some years.

The preparation (whether in the recent state, or having been preserved in spirit or in solution of any sort) is wiped nearly dry, and then arranged, so as best to display its peculiarities, upon a wooden slab of the required size and shape, this having been previously saturated with water, and wiped nearly dry.

Having been slightly fastened to this slab by means of pins, and all those parts in the subsequent relieving of which any difficulty is to be apprehended having been supported or filled up with moistened linen rag, the whole is immersed slowly and gradually (at an angle of 40 to 45 degrees) in the melted composition.* Being withdrawn

* This consists of Burgundy pitch and pure bees' wax, each one pound; yellow resin, two

for a few seconds, it is again and again dipped so as to produce a mould of suitable thickness. This being effected, it is plunged into cold water, when the mould becoming hard, the pins may be easily withdrawn, and the slab and preparation readily taken out of the mould.

The mould is then to be carefully filled with the finest plaster of Paris in the usual way, and in half an hour after this has set, it may be placed for a few minutes in water a little below blood-heat; by this means the mould becomes soft and pliable, and may be easily torn off, bit by bit, in such a manner as to leave uninjured the most delicate part.

Immediately after the removal of the mould the cast should receive two or three coats of the finest olive or almond oil; when this has been absorbed, we may begin at once to colour from nature, using at the same time a small quantity of fresh ox-gall.

The time occupied by the whole process is so short, that the colours of the original generally remain fresh for the imitation of the artist upon the cast.

Those of your readers who may wish to see some of the casts will find one or two in the museum of the College of Surgeons, also at King's College, and at St. Bartholomew's and Middlesex Hospitals, London; and at the Medical Library in this town.

I remain, sir, your's, &c. &c.

WILDMAN WHITEHOUSE.

Liverpool, September 13, 1838.

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

The Spas of Germany. By A. B. GRANVILLE, M.D. F.R.S. &c. Second Edition. London, 1838. 8vo. pp. 516, and lviii. With 39 Illustrations and Maps.

BATHING, in all its varieties, and the drinking mineral waters, are certainly two of the most pleasant prescriptions in medicine and hygiene. Purgative

oz.; mutton-suet melted and strained, six oz. This should be kept in a fluid state, and at a regular temperature, by means of a lamp placed under the containing vessel, the most convenient form for which I have found to be a longitudinal section of a cylinder, the flat side being of course the lower side, or inclined plane, on which the bottom of the slab slides during its immersion.

and tonic draughts are made un-much better in the bowels of the earth than in Bond Street or Holborn; and bathing, when not limited, as it too often is in this country, to cold bathing, is at once a preventive of disease, and a palliative of half the ills that flesh is heir to. The cold bath, admirable as far as it goes, suits only a small part of the population for a few months in the year. The warm-bath, great as is its efficacy when administered even in the ordinary manner, becomes doubly powerful when the skin is stimulated by the saline or gaseous ingredients of certain springs, and when the patient, "long in populous city pent," at the same time enjoys the air of Barèges, Harrowgate, or Baden. This adjuvant of a pure atmosphere doubles the advantage of drinking likewise; and though we would by no means depreciate the benefit to be derived from taking Cheltenham or Selters water in London, we would say to every patient, go to the fountain if you can:—

"Nam quantumvis sapor est allatâ dulcis in undâ,
Dulcius ex ipso fonte bibuntur aque."

Of the boundless advantages to be derived from the waters of many celebrated springs, we have not the smallest doubt; and we therefore rejoice in the publication of Dr. Granville's discriminating work as an excellent flapper to many jog-trot practitioners, who, amid the routine of blue pill and black draughts in smoky cities, forget that there are such things in the world as pure air and saline springs. As for settling the precedence of all the healing waters in Europe, it is fortunately not our office. Baden has cured many cases of gout, but so has Bath; and Harrowgate, if its records were unrolled, might prove a rival to Aix-la-Chapelle itself. For our own part, if we may tell our private opinion so publicly, we should prefer the watering-places on the other side of the channel; and if, some day, our stomach should sink under our literary labours, and any friendly counsellor should recommend Tunbridge, we should be tempted to ask, "Would not Pyrmont do as well?" To us the prolonged travelling, the strange sights and sounds, the sociability of a foreign Spa, and the unceasing vivacity of its *table d'hôte*, would be so many additional tonics; while, to a quiet septuagenarian, who had never before left his native country, they

might be more depressing than a dose of colicium.

The work before us commences with popular considerations on the use and power of mineral waters, extending to about thirty pages; and we then come to the body of the work, where we find the Spas divided into four geographical groups. The first contains the Baden and Württemberg Spas, consisting of Baden-Baden, Rippoldsau, Wildbad, Liebenzell, Deinach, Cannstadt, and Boll.

Baden, which is the first on the list, is the first also in desert, and perhaps the only one of the seven which enjoys a European reputation. It takes its double name from being in the Grand Duchy of Baden, and is thus distinguished from Baden near Vienna, and Baden in Switzerland. Although its healing springs have been celebrated in Germany for ages, and seem indeed to have been known since the time of the Romans, their fame had hardly penetrated to England in the middle of the last century; for in one of Chesterfield's Letters to his Son we find the following curious passage:—

"You tell me that you are going to the baths of *Baden*; but that puzzles me a little, so I recommend this letter to the care of Mr. Larpent, to forward to you; for Baden I take to be the general German word for baths, and the particular ones are distinguished by some epithet, as Weissbaden [Wiesbaden], Carlsbaden [Carlsbad]," &c.

At present, however, the case is widely different; not to know Baden would argue oneself unknown; and, as our author observes, it is "justly considered the queen of the Spas of Germany, Carlsbad claiming to be the monarch of them all." (p. 4.)

There are two obvious methods of reaching Baden from London; the one to go by Paris and Strasburg; the other to travel by way of Ostend, or Antwerp, and the Rhine. The latter road looks rather longer of the two on the map; but from the facilities afforded by the Belgian railroads, would probably be full as short in point of time. In either method it is easy to reach Baden in four or five days.

The principal spring at Baden is called the *Ursprung*, of which the temperature is $153\frac{1}{2}^{\circ}$; a pint contains $23\frac{3}{5}$ grains of solid matter, of which

sixteen are common salt. "Next in importance are the sulphate, muriate, and carbonate of lime, which altogether amount to six grains and a half. The remainder consists of a small portion of magnesia, and of traces of iron, with about half a cubic inch of carbonic acid gas in addition." (p. 18.)

The water is conveyed by pipes into several of the hotels, such as the Badischer Hof, the Zähringer Hof, &c., so that the invalid may bathe without going out of the house, and that at the most moderate rate. At the Zähringer Hof, for example, the price of an ordinary bath is twenty-four kreutzers, or eightpence.

The waters of Baden are indicated, according to Hufeland, in all kinds of paralysis, contractions, gout and rheumatism, cutaneous eruptions, ulcers, and cold swellings.—(*Practische Uebersicht*, &c. p. 249.)

Dr. Granville also mentions some cases of amenorrhœa which were cured by these waters when every other remedy had failed.

On the other hand, there are many cases in which they are contra-indicated:—

"The operation of bathing in water endowed with much power, from heat and other circumstances, is not to be viewed lightly. Much mischief has arisen—nay, fatal results have followed—from its indiscriminate adoption. A rich merchant, who, but a few hours before, had been noticed on the public promenade after dinner, on the day after our arrival was found dead in a bath at eight o'clock the same evening. A lady was pointed out to me, who had lost the use of her limbs, after taking three hot baths, without having first considered the nature of her case, or followed the instructions generally given for using them. There are certain conditions of the body which render these hot baths inadmissible. In such cases, to attempt them, or to persevere in their use, is to rush into danger. Such as have a full, heavy, and distended liver; others who possess very weak powers of digestion, and at the same time suffer from accumulated phlegm in the stomach, and crude or foul secretions in the intestines; a third class, whose strength has been wholly annihilated by a long and dangerous illness; lastly, people naturally inclined to collections of blood in the

vessels of the head, and subject to giddiness, palpitations of the heart, or who have had a threatening of apoplexy: all these must abstain from the hot bath at Baden, if they care for their safety."—(P. 19-20.)

We, of course, agree with our author, that the hot bath would be inadvisable for the patients described in the above extract; but must they all avoid the warm bath also? He afterwards says, "Let the temperature never exceed 100°; and oftener let it be between 94° and 98°." Would not many of them benefit by a bath at 94° or 96°? We confess that we ask doubtingly, on account of the difference between ordinary water and the stimulating streams of Baden. By the by, when we took a bath there last year (at the Badischer Hof, if we recollect aright), its temperature was scarcely high enough, and the pipe which should have let in hot water conveyed lukewarm instead. The waters are also drunk, and the carbonate, muriate, and sulphate of soda, are often added to them, so as to produce a faint imitation of the Carlsbad water. Living, and luxurious living too, is extremely cheap at Baden. "A *déjeuner Anglais* is thirteen pence; a *déjeuner simple*, with coffee and bread and butter only, twenty-four kreutzers, or eight pence. The early dinner at the table-d'hôte is one florin, and fourpence more for half a bottle of Durbacher, *vin du pays*. At four o'clock the table d'hôte dinner is three francs (2s. 6d.) with wine, and without it one florin and twelve kreutzers, or two shillings. (P. 39)

An English physician, Dr. Hutton, of whose merits our author speaks in high terms, has settled in Baden for the season, so that the countrymen unskilled in the tongues may have their ailments attended to without the risk of mutual misunderstanding.

Of Kippoldsau our author says little, and we shall say less. It is a cold saline spring in the Grand Duchy of Baden, resembling Seltzer (Selters) water in taste.

Wildbad is situated in the kingdom of Würtemberg, at a short distance from Baden-Baden, from which, however, no direct road to it is given on our author's map. The temperature of the waters varies from 84° to 100°, the Herrenbad being of the latter degree.

The Fürstenbad, or Prince's Bath, looks wonderfully tempting in the woodcut at p. 59. It has been built over the spring, and has a fine sandy bottom, and a temperature of 98½°, just near that undefinable limit which separates the warm from the hot bath. Our author describes the delightful tranquillity which it produces, with great elegance of language, p. 58-9. He concludes by saying, "From such a position I willingly would never have stirred. To prolong its delicious effects, what would I not have given? But the Badmeister appeared at the top of the steps of the further door, and warned me to eschew the danger of my situation: for there is danger even in such pleasures as these if greatly prolonged."

[To be continued.]

MEDICAL GAZETTE.

Saturday, September 29, 1838.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."
CICERO.

A WORD OF ADVICE TO PUPILS.

WE never remember the first of October to have approached with less noise or bustle than this year: there are no new schools, and no great changes in the old ones; and the market (to use a language which is daily becoming more appropriate in the schools) looks unusually dull and heavy. A good deal of preparation, however, has been going on during the past year; and it has been not a little amusing to us, to sit by and silently watch the schemes that have been employed to accumulate in one season a reputation for the next. It seems that as competition increases, and the profit of teaching becomes less, the exertions to obtain the little that can be made by it become daily greater; and hence it is, that throughout the year some of the teachers have been conti-

nually endeavouring to set up some new attraction to tempt those who may arrive at the ensuing season.

Now it argues but little for the judgment of those who are about to enter the medical market for the first time as consumers, that the sellers should deem it best to vaunt the worst qualities of the goods they offer. Yet so much is this the case, and so boldly are those things which are injurious puffed up as beneficial, that we gave a general caution to students this time last year, to beware of all schools which loudly professed to offer any peculiar advantages. But we fear that our advice was scarcely definite enough, and that it is necessary to particularize more exactly the *advantages* which are especially to be avoided.

Let us pass in review the chief attractions which we have seen exhibited, and which are the most frequently resorted to, to gain a reputation for the schools. Perhaps the most common is what is called "bold practice." It is quite extraordinary how fascinating this is to young men. We have often seen the student of one hospital, whose physicians were prudent and judicious men, looking quite small, while another from the class of a more *bold* practitioner was romancing on the prowess of his preceptor, who was making poisons his playthings. Gentle reader! if you be a pupil now doubting under whom you should study the practice of medicine, receive this word of advice: if ever you see a physician tossing about huge doses of arsenic and prussic acid, of morphia and strychnia, like so much magnesia—if ever you hear one (as we have heard) ordering five or six of our most powerful poisons in a single draught—if ever you see a patient living(?) on a diet of hydriodate of potash—beware of such teacher; and if you hear him with a sneer of contempt laugh at

the "old women" who deal carefully with these things, leave the district at once; for if you remain there, you will learn more of the arts of manslaughter than of the mysteries of medicine.

Observe the same rule with regard to "bold" surgeons, as all the imprudent ones are called. If an hospital be renowned for the number and severity of the operations performed at it, it should be avoided, however attractive it may appear by this blood-red light. There is no more dangerous qualification, even in one whose anatomical knowledge and dexterity are of a high order, than this *boldness*; and such a surgeon should never be a teacher, for although he may do no great mischief, his pupils will accomplish plenty; because boldness is so much easier to learn than anatomy, and the daring to attempt an operation is so liable to be mistaken for the ability to perform it. Nothing can be more in point than the maxim of that great surgeon, the late Mr. Cline, with whose lectures the present volume opens. "Those who are not in the habit of operating, should endeavour to operate slowly, not considering the time it will take, but in what way it may best be done." If, therefore, you hear much boasting about operating against time, and removing portions of the sphenoid bone; if you see men cutting into hernial sacs and urinary bladders at first incisions, amputating legs and arms without either mercy or a tourniquet; twisting femoral and tracheal arteries, and slicing human flesh like so much cat's meat, eschew them all most scrupulously. They are but a kind of carpenters, who are dignified somewhat by the material that they work in. Besides, in all these things you should carefully keep in view to learn that which will be most constantly useful in your own practice in after

life, when you will, in all probability, very rarely be called upon to perform any such operations, but will be daily required to exercise that judgment which professed operators so rarely possess, and to cure those simple diseases which they and their followers despise and are ignorant of.

For the same reason, be very cautious of the places which boast of, and are renowned for the number and imagined importance of the accidents which are carried to them. Remember, that accidents are important in direct proportion to their frequency, and inversely as their severity.

Next to these, the attractions of tragedy, the most enticing baits held out are those of novelty; and amongst these what can compare to Animal Magnetism, *redicivus*—though now *remortuus*? Its suffocation has certainly been most lamentably untimely: what a figure might it not have made in the *carte* of its foster parents! What a bright beacon might it not have shone around the brows of its sponsors! How had it promised to repay them, had it been permitted to survive till another October! But they are left with no other consolation than the excellence of their intentions may afford them; unless, indeed, they will be glad in having afforded an admirable caution to those who come after them to be wary of revived follies, and will allow that which was intended for a harbour-light to remain burning to indicate where there are shallows. Now let the student remember the fate of animal magnetism, and that of at least nine-tenths of the novelties that are brought out and vaunted to attract attention: creasote, at first the specific for phthisis, epilepsy, and porrigo—now little more than an occasional cure for the tooth-ache; strychnia, once the panacea of paralysis and every nervous disorder now known for scarcely more than the mischief that

it does. Let him look, too, at the wreck of homœopathy, that refuge for the destitute of quacks, and at the shadows that now alone remain of all the systems born and defunct in the last ten years. Let him look with suspicious eyes on all teachers who are perpetually harping upon novelties.

We have had of late, too, some strange reports of royal roads discovered to the attainment of some of those high regions of medical science which were hitherto thought most difficult of access. But, if you hear where it is that you can learn the use of the stethoscope in an hour, or where you can be taught lithotritry or lithotomy in a day, or any easy mode of accomplishing the greatest difficulties, just ask whether the same teachers do not offer you some other unusual *advantages*; and if they do, leave them at once. There is no royal road to medical skill, though there may be to certain kinds of medical practice; and steam is, as yet, in the infancy of its application to the study and practice of the healthy art.

Avoid, also, those who profess themselves to be great men in some one thing; rely on it they are but little men in all others. If you see one riding a hobby very hard, keep out of his way; whether that hobby be a stethoscope or a lancet—a new knife or an old function: one horse will never carry either him or you to professional competency.

Numerous attractions of less note and less mischief have been held out, and vaunted with scarcely less noise; such as the opportunity of dissecting by gas-light, of reading Moliere's *Malade Imaginaire*, and Andral's *Anatomie Pathologique*, with a native, under the name of a teacher of Medical Classics—of being taught with strict reference to the questions asked at the Hall and College, and so on. But avoid them all—they are fraudulent blinds to conceal real disadvantages; leave them, and ask,

where the opportunities are offered for a personal and practical study of your profession—where you can see disease of all kinds and in all its forms—where you can learn the value of remedies which you may administer without trembling—where you may be guided in your studies by men of judgment, experience, and carefulness, who can endure to pass a year without exhibiting a new folly; who would rather *not* operate when the question of maiming a patient, or leaving him with whole limbs, is nearly equally balanced; or who, where a fatal result is inevitable, would rather have a man die of his disease than be poisoned by the remedy. Seek out these schools, (and you must seek for them because *their* names are not cried aloud in the streets) where you have the best opportunities of dissecting for yourselves—of studying morbid anatomy in museums and in the dead-house—of reading and referring to libraries—of learning the collateral sciences, as chemistry, botany, &c. strictly in their relations to medical and surgical practice; in short, of acquiring a sound and practical knowledge of your profession; and though the road to it by them seem rather long—though it is neither lighted up by the *ignes fatui* of novelty, nor its scene diversified by tragedy and bloodshed—go to these schools and hospitals, and work on steadily and quietly till you are fit to pass the ordeal, not only of your examinations, but of your own conscience, when you come to have the lives of your fellow-creatures, and perhaps your friends, entrusted to your care.

OUR NEW VOLUME.

WE think it right, in commencing a new volume, to intimate that it is our intention to pursue the same general plan on which this journal has been hitherto conducted; and we do this with the

greater confidence, as we have the satisfaction of being able to state that the patronage bestowed upon the MEDICAL GAZETTE has very materially increased during the past year, both with respect to its circulation and the number and value of the communications which it has been the medium of giving to the public. We have every reason to hope that this source of supply will continue open to us. At the same time, we have deemed it to be our duty to secure a stock of original materials in the form of Lectures. This department will comprise a short elementary course on some of the most important points in surgery, by the late Mr. Cline, which we trust will be acceptable to our readers, not less on their own account than from their recording the opinions of one of the most eminent surgeons England ever produced, but who has published less than, perhaps, any other individual who had obtained equal celebrity. In the department of surgery we have also procured clinical lectures, delivered in the class rooms of Sir Benjamin Brodie and Mr. Lawrence. In medicine we have the very valuable co-operation of Dr. Graves, a set of whose clinical lectures we shall commence next week—while, on Diseases of the Eye, we are indebted to one of the most distinguished writers of the day on Ophthalmology—Dr. Mackenzie, of Glasgow. After the conclusion of this last we purpose to give a set of lectures on the same subject by M. Velpeau, published under his express authorization, and which will be found to contain views considerably different from those of the English and German surgeons. It is also probable that we may be enabled to publish some valuable lectures on the Chemical History of Calculous Disorders, by Dr. Venables; but we are not yet quite certain whether we shall be able to give them in the present volume.

GLASGOW EYE INFIRMARY.

CLINICAL LECTURES BY DR. MACKENZIE.

Sept. 15, 1838.

Lenticular Cataract—Operation of Extraction.

ALEXANDER CLARKE (No. 8748), an iron-dresser, aged 70 years, admitted 24th August, 1838. For three years back, the vision of left eye has been failing. The lens is now opaque, the opacity of an ashy colour, somewhat striated towards the circumference. The right lens presents the first stage of glaucoma*, with incipient cataract; and the vision of this eye is declining. No headache. Pupils at present fixed, from the use of an infusion of belladonna. Pulse 84. An ounce of castor oil to-morrow morning.

26th.—After the punctuation and counter-punctuation with the extraction-knife, through left cornea, were effected, the edge of the knife being directed upwards, with the intention of dividing the upper segment, a quantity of vitreous humour was discharged. The knife was immediately withdrawn, and the eye now appeared flaccid. The needle, bent at a right angle, was introduced through the cornea, and the capsule opened. With two strokes of David's scissors the incision was now completed. During these steps of the operation it was with great difficulty that the patient could be brought to direct his eye downwards. The lens was now removed by the ordinary degree of pressure, and without any farther loss of vitreous humour. The aqueous chambers became immediately filled with red blood, probably in consequence of the iris having been wounded with the scissors. The eyelids, on each side, were brought together with a strip of court-plaster.

27th.—No pain. Pulse slow and intermittent.

29th.—Two colocynth pills.

30th.—Blood appears to be completely absorbed. Pupil clear. Sees the fingers and other objects before him. Has not been permitted to open the eye sufficiently for the wound of the cornea to be seen. Strips of plaster again applied.

Sept. 2d.—Eye opened for the second time. No pain, nor sign of inflammation. Cornea clear, and vision good. Strips of plaster again applied.

4th.—Eye opened for the third time, but not exposed to a full light. Expresses himself much satisfied with the distinct vision he has of the objects presented to him.

8th.—Tells the hour by the watch, with-

out any cataract-glass. Plasters still applied.

9th.—A colocynth pill.

12th.—Wound of cornea appears perfectly healed. Pupil angular towards nasal side of eye. Bowels rather bound. Two colocynth pills. Extract of belladonna to left eyebrow.

13th.—Pupil pretty widely dilated, and very clear. A small tag of adhesion between nasal side of iris and nasal extremity of cicatrice of cornea. Belladonna washed off.

15th.—With a $2\frac{1}{2}$ -inch convex glass reads a large type.

I dare to say, that some of you, who saw the extraction of the cataract performed on Clarke, thought very unfavourably of its probable success. It is difficult to conceive an eye to look worse than his did, filled completely, as the aqueous chambers were, with red blood, and so strong a likelihood existing that some important part had been wounded in the operation, besides those which are unavoidably implicated. Our fears have been happily disappointed, and Clarke appears to be restored to as good vision as is generally obtained by any operation for cataract.

With regard to an operation so important as extraction, no particular, however minute, ought to escape your attention. When you witness an extraction, you should note every circumstance, and weigh considerably its influence, whether favourable or unfavourable, on the result of the operation. The circumstances of an unfavourable nature you should particularly study, in order that you may avoid them in your own operations.

1. You would observe that before proceeding to operate on Clarke's left eye, we tied up his right. We think this practice tends to keep steadier the eye which is to be operated on. If the patient sees considerably with the other eye, which is often the case, the tying of it up prevents him from starting at the approach of the knife.

2. We laid Clarke in the horizontal position, on his back, as this secures the steadiness of the head. It also tends to prevent syncope, an accident which, with the patient sitting up, is exceedingly annoying in the midst of such an operation as extraction.

3. We tried the point of the knife on a bit of thin leather, held on the stretch, that we might ascertain its fitness to penetrate so dense a structure as the cornea. If the knife passes through the leather without causing any sound, the point is perfect; if a crack is produced at the mo-

* See MEDICAL GAZETTE, vol. xxii. p. 107.

ment of its passing through, the point is bad, and another knife is to be taken.

4. To the assistant was committed the supporting of the upper eyelid, while with the forefinger of my left hand I depressed the lower eyelid, and placed the middle finger on the *caruncula lacrymalis*, so as to prevent the eyeball from turning inwards. I have often said that this last is one of the most important directions out of all those which respect extraction; for, if after commencing the operation, after performing what is called the punctuation of the cornea, you allow the eye to roll towards the nose, so that the nasal edge of the cornea is hidden from your view, you will find it difficult, or impossible, to recal it to the central position. If you now go on with the counter-punctuation you will be obliged to perform it in the dark, and will probably perform it wrong, either bringing out the knife too far from the nasal edge of the cornea, and thus making too small an incision, or plunging the instrument through the iris and through the sclerotica.

Some operators use no assistant. It is only for those who are experienced and dexterous to attempt this, and even with them the practice does not always answer. If the fingers of the hand which does not hold the knife be occupied in keeping the eyelids asunder, it may be impossible for the unaided operator to prevent the turning in of the eye.

Barth, professor of anatomy at Vienna, and the founder of the Austrian school of ophthalmology, was one of those who operated without an assistant. He kept the patient standing, with the head against the wall. Santerelli has related the particulars of a double extraction by Barth, which I shall translate to you.

"The celebrated Barth," says he, "oculist at Vienna, boasted that he operated without an assistant and without a speculum. Happening to be a second time in that capital, in 1795, on my return from England, and being particularly introduced to him, he permitted me to be present at an extraction of the cataract, which he performed on the 10th of April, at half past 11, A. M.

"The patient was a lady, of about 60 years of age, cataractous in both eyes, cachectic more from age than constitution, whose case I put down in my journal. The cataracts were of a blue colour, tending to whitish. The operator made the patient stand up by the side of a window which looked to the south, in such a way that her left eye was turned towards the window. He took off his coat that his arm might be more at liberty. He then applied the point of the forefinger of his

left hand against the upper edge of the left orbit, and thus keeping the upper eyelid raised, with the thumb of the same hand he depressed the lower, so that the eyelids, with their tarsi, formed something like the mouth of a little purse, within which moved the eyeball.

"The lady was desired to look the professor in the face and somewhat outwards. At that moment the operator took his little knife, which he had between his lips, with the thumb and forefinger of his right hand, and touching the cornea with the flat side of the knife, to accustom the patient, as he said, to the new impression, he placed the point in the middle of the external edge of the cornea, where he meant to begin the incision. Although the mobility of the eye prevented that, the operator, confiding in his dexterity, struck the cornea, and with the point of the knife reached as far as the pupil. At that instant the lady turned the eye so much inwards, as to hide a good part of the cornea, on which the operator withdrew the instrument, allowing a considerable part of the aqueous humour to escape.

"Not choosing to prosecute the operation further for the present, he placed the patient at the opposite side of the window, and proceeded to operate on the right eye, leaving the left free, as he had done the right, when he operated on the left. Having fixed the eyelids with the fingers of his right hand, and this eye not being quite so restless, he penetrated its cornea at more than a line from the sclerotica, and pushing the knife on, reached with it the opposite side of the cornea, which he ran through, and allowing the eyelids to fall together, terminated the inferior incision of the cornea almost with the eye shut, by which means he lessened the dragging of the part to be divided.

"That done, he rubbed the eye gently with the point of his thumb, in order that the parts might recover themselves; and quitting the right eye, he quietly returned to the left.

"Having with some difficulty placed the lady in her former position, he tried repeatedly to thread with the point of his knife the opening formerly made, and at last succeeded, but not without some trouble. He advanced the point, with difficulty, through the anterior chamber, on account of its narrowness, arising from the loss of part of the aqueous humour. The lady turned the eye under the inner angle as at first, but the professor, recalling imperiously the eye into the middle*, was able to

* "Recalling imperiously,"—a strange phrase! but so it is. "Richiamaudo con imperio l'occhio nel mezzo."

traverse the cornea on the other side, at a line's distance from the sclerotica, and lower down than the puncture made at the outer edge; and having terminated thus the inferior incision of the cornea, he allowed the eye to rest. He then took the cystotome of La Faye, and opening the eyelids as before, introduced it through the anterior chamber, as far as the pupil, to divide the capsule; repeating this, indeed, twice.

"On opening the capsule there issued a little whitish humour, which caused the professor to say, that the cataract was milky. He then took a little golden spoon, and compressing with it the lower part of the eye, solicited the exit of the lens, which was accomplished with great difficulty, on account of the wound of the cornea being rather small. From the little consistence of the lens, and not from its being milky, there had at first issued the humour of Morgagni somewhat changed, and this ought to have made the exit of the lens easy, through a moderate opening of the cornea.

"Notwithstanding repeated attempts, and gentle skilful compressions of the eye, the pupil remained somewhat turbid, perhaps on account of opacity in the capsule, and the operator contented himself by leaving the issue to nature. Without changing the position of the patient, he introduced the cystotome into the right eye, and with more facility. The capsule being opened, he took the spoon with which to compress the lower part of the eye.

"From this compression there likewise issued a little whitish fluid, followed by the lens, of a whitish colour and somewhat hard. Its exit was attended with some difficulty, this opening not being exactly proportioned. The extractions being thus terminated, he rubbed the eye gently, in order that the parts might resume their places; and on trying the vision, the left eye saw none, the right could distinguish objects sufficiently well.

"The operator being of opinion that the operations had not gone off in the masterly style he would have liked, said to those present, with much frankness, that *one did not always gather roses*; to which some one replied, that *that should not signify to one who had already gathered so many*."

I have quoted this lively narrative to shew you that even in the hands of the most expert, the plan of operating without an assistant is apt to give rise to that turning of the eyeball inwards, which is productive of much annoyance to the operator, and may even lead to the most disastrous consequences.

5. The eyelids being fixed and the eye-

ball prevented from turning itself inwards, I proceeded to open, with Beer's knife, the upper half of the cornea. This is exactly the reverse of the plan which I was taught by Beer to consider the best; and I may take this opportunity of saying a few words on the history of the upper section, and on its advantages.

When I was a pupil at Vienna, some twenty years ago, it was usual to attribute the invention of the upper section to Santerelli, and to swear, *in verba magistri*, that it was a bad operation. You will find it set down in books, that Wenzel, Richter, and Benjamin Bell, practised, or at least recommended, the upper section. The first Wenzel's common operation was a semi-lateral section, parallel to the temporal and lower edge of the cornea; but in certain cases, as when the lower part of the cornea was leucomatous, he made his section parallel to the nasal and superior edge. In this way he operated, as his son relates*, on the Duke of Bedford and on the celebrated Leonard Euler. All that Richter says on the subject†, is, that the upper section is practicable. Bell had tried the upper section only on some of the lower animals; but he states distinctly‡ several reasons for preferring it to the common method of making the incision parallel to the lower edge of the cornea.

Santerelli was the first, as far as I know, who actually made the section, not semi-laterally as Wenzel had done, but at the upper edge of the cornea. This he did at Berlin, in 1795, with a double-edged knife, the figure of which you see here. He in-

troduced the point of the instrument directly into the anterior chamber, from the middle of the upper edge of the cornea; a method of operating, in which, I know from experience, it would be impossible to make a section of more than from a quarter to a third of the circumference. This method of Santerelli's is a bad one, and is entirely abandoned.

The best operators, both of this country and of continental Europe, are at present exactly following the plan recommended by Benjamin Bell, who says, "The upper part of the cornea is cut with the same ease as the under part of it; the same instruments being employed, and the surgeon, patient, and assistants, being placed in the same manner: only in this case the knife

* *Traité de la Cataracte*, pp. 132, 135, Paris 1786.

† *Treatise on the Extraction of the Cataract*, p. 59, London 1791.

‡ *System of Surgery*, vol. iv. p. 238. Edin. 1801.

* Santerelli, *Delle Cataratte*, p. 61, Forlì 1811.

must be introduced with the cutting edge of it towards the upper part of the eye."

Now, there is no denying this, that though the mere section may be executed "with the same ease," the whole operation of extraction, at the upper edge of the cornea, is more difficult than if the incision were made downwards. This is particularly the case with regard to the second period of the operation, or the opening of the capsule. You saw this in Clarke; and I have repeatedly found it difficult, and once I found it impossible, to get the eye turned down sufficiently to permit me to open the capsule. In the case in which I found it impossible, I ventured to proceed to the third period, the exit of the lens, without having performed the second; and by a moderate and sustained pressure I was lucky enough to get away the cataract, without any loss of vitreous humour.

To counterbalance this difficulty of performing the second period of the operation, which constitutes the principal objection to the upper section, we have two great advantages:—1st. The flap of the cornea, completely covered and protected by the upper eyelid, unites more readily and with greater certainty, so that in general there is less inflammation, and very rarely any suppuration or any prolapsus iridis. 2d. Should unfortunately inflammation come on, and a broad white cicatrice be the result, with perhaps adherent and distorted iris, or even closed pupil, the lower half of the cornea remains transparent, and by and by we are able to form an artificial pupil in the lower half of the iris, through which the patient will generally see as well as if the eye had a natural pupil. The same degree of inflammation, opacity, and adhesion, following the lower section, would produce an impediment to vision, in its usual direction of downwards and forwards, which an artificial pupil in the upper half of the iris would obviate only in a very imperfect degree.

6. As soon as I had made the punctuation and counter-punctuation of the cornea, not merely the aqueous but part of the vitreous humour was seen to escape from Clarke's eye. I immediately withdrew the knife, leaving a considerable bridle of the cornea uncut—a practice which I remember Mr. Abernethy stating, in his lectures, to have been followed in all cases by Mr. Phipps, with a view of avoiding the danger of the vitreous humour suddenly escaping sometimes along with the lens, at the instant of finishing the section in the common way. Sir Wathen completed the section, I presume after performing the second period of the operation, with a small blunt pointed knife. The loss of vitreous humour was not great in Clarke's case, and the effect

on vision has been null; confirming, on this point, the opinions of Beer and Roux, both of whom have regarded the loss of a small quantity of vitreous humour as of no consequence. Nay, Mr. Lawrence thinks, that "in many instances it seems rather to contribute to success: it lessens," he says, "the bulk of the globe, and takes off the tension which occasionally succeeds to the operation*."

7. The capsule being freely opened in the ordinary way, I proceeded to divide the bridle of the cornea, but here I experienced very great difficulty. The patient could not turn his eye sufficiently down to permit me to see the blade of Daviel's scissors pass into the anterior chamber, so that I was obliged to perform this under cover of the upper eyelid, and no doubt gave the iris a small snip along with the cornea. To have divided the bridle with Mr. Phipps' knife would have been absolutely impossible. The lens was easily extracted without the use of the hook, which I generally employ when the vitreous humour threatens to escape. Its exit was immediately followed by a discharge of blood, from the iris into the aqueous chambers. The case which I have read from the case-book, details the re-absorption of the blood, and the favourable issue of the operation. The tag of adhesion between the iris and the nasal extremity of the cicatrice does not in any material degree interfere with vision.

8. Our patient was kept with both his eyes closed, by strips of court-plaster, for nearly a fortnight—a practice which I consider of great utility. The plasters protect the eye from the intrusion of foreign matters, prevent the patient from using the eye, and cause the eyelids gently to compress and close the wound of the cornea.

WESTMINSTER HOSPITAL.

Traumatic Delirium relieved by the exhibition of Opium.

THOMAS HOLMES, a large and powerful man, about 50 years old, was admitted, under the care of the senior surgeon, on the 22d of August last. The patient having been occupied for many years as a coal-heaver, in the Westminster gas factory, had addicted himself to free potations of malt and spirituous liquors, a custom which the laborious nature of his duties justified to his own mind. The plea for his admission was an injury to the forearm, which was highly inflamed and tumefied. Two days previously, whilst carrying a heavy load,

* Treatise on the Disease of the Eye, p. 425, Lond. 1833.

he fell upon his left arm. He felt a great deal of pain in the part, but continued his occupations till the close of the day. The next day he remained at home, unable to work, and suffering greatly.

When admitted, the swelling obscured the nature of the injury, but the house-surgeon, suspecting a fracture, placed him in bed, ordered him a low diet (in which tea is the most stimulant beverage permitted), and having placed the affected limb on a pillow, caused leeches and lotions to be applied. Some sympathetic fever also existing, he gave the patient saline aperient medicines. These remedies effected but little benefit. On the evening of the 24th August, Holmes became exceedingly restless and irritable, and at 10 P.M. he was perfectly delirious. He imagined himself surrounded by hideous monsters, from whose power he was making perpetual efforts to escape. All the voluntary muscles were tremulously agitated, and his eyes, lips, and *alæ nasi*, in continual motion; the conjunctiva of both eyes was injected, and the pulse rapid, but feeble. Half a grain of muriate of morphia was now administered, in the shape of a pill.

25th.—The patient had a good night's rest. The pulse, however, still remained small and rapid, and the tongue was brown. Though much quieter than last night, he is yet under the influence of his illusions. He is now ordered ten drops of laudanum every four hours, with ammonia and camphor julep in the ordinary doses. Having swallowed two doses of this mixture, the symptoms returned with redoubled violence, and it became necessary, for his own sake, to restrain the patient with a straight-waistcoat, and, for the sake of his fellow inmates, to place him in a separate apartment.

4 P.M.—The poor fellow still continues violent, starting up frequently, struggling to extricate himself, and remonstrating in a ludicrous manner with his attendants.

Half a grain of Morphia now administered.

10 P.M.—The morphia has produced no palpable effect. He has been very unruly, shouting and talking perpetually.

A grain of Acetate of Morphia administered.

26th.—The effect of the morphia became visible a short time after its administration. The patient had some sleep in the night, but the delirium is as violent as ever this morning. He refuses all medicine; he is perpetually muttering and talking, and every limb, if not every muscular fibre, is in continual action. He is

bathed in perspiration. The pulse is as rapid and feeble as ever.

Thirty minims of Battley's solution of Opium now given to him.

1 P.M.—A grain and a half of Acetate of Morphia exhibited.

5 P.M.—No material amendment has occurred. A drachm of Battley's liquor, in a solution of starch, injected into the rectum.

10 P.M.—The delirium is apparently unassuaged.

Two drachms of Battley's liquor thrown into the rectum.

Midnight.—He is tranquilly asleep.

27th.—Holmes slept well all night, and he is quite rational this morning. The pulse is 60 and soft, and the tongue moist, but whitish. He is in low spirits. The bowels being confined, a dose of calomel and colocynt is administered.

The forearm is now carefully examined, and the tumefaction having very much abated, Mr. Dasent has ascertained the injury to be a simple fracture of the radius and ulna. The forearm is placed in splints.

31st.—The poor fellow is rational and cheerful; his countenance is perfectly tranquil; the cuticle covering the lips is exfoliating; the tongue is highly furred; the bowels act regularly. He has no headache, and sleeps well. He has swallowed small doses of opium daily, but he is still on low diet.

September 4th.—The patient is convalescing.

21st. — Quite recovered, but he still wears splints on the forearm.

Abscess of the Os Femoris, cured by Trepanning.

Isaac Childs, 33 years of age, a patient of Mr. Lynn's, has an oblong granulating sore, extending in a line from the trochanter major of the left thigh to the length of about six inches towards the external condyle, along the outer edge of the vastus externus. Small spiculae occasionally exfoliate from the femur, keeping up much constitutional irritation. He has often a dull pain in the trochanter major. The muscles of the thigh are much atrophied, and the outline of the femur is consequently easily traceable by the eye. The man spends his time principally in bed, and presents an unhealthy and pallid appearance.

The patient has the greater part of his life been occupied as a labourer. In early life he had contracted the venereal disease several times, and had taken a vast quantity of mercury, and suffered frequent and severe pyalism. In course of time, secondary symptoms developed themselves; pains in the bones, nodes, sy-

philitic lichen, but no sore throat. These were removed by blue pill and sarsaparilla. With a naturally weakly, phlegmatic constitution, thus further debilitated by disease, he was in an evil hour induced to enlist in the Britannico-Iberian Legion, and accompanied his regiment to the Peninsula. There, after a very little campaigning, his old rheumatic or venereal pains returned; an acute pain extended outside of the thigh, from the trochanter to the condyle. An abscess formed and broke about six inches below the trochanter. Similar apostemata appeared upon various points of the surface, such as the throat, the nape of the neck, the thorax, &c. From these, pus flowed copiously, and was of a laudable colour and character. He was placed under the care of Mr. Rutherford Alcock, the inspector-general at the Convent of San Telmo, St. Sebastian. He was treated in that hospital for many months, but the abscess could not be got to heal, although the patient was placed in circumstances most favourable for recovery. He was accordingly discharged as unfit for service in July 1837. On his return to London, he became an inmate of St. Bartholomew's Hospital. Mr. Skey made a long incision downwards from the trochanter in the course of the *linea aspera*. A seton was then inserted in the integuments, from which he derived some ease. After his dismissal from St. Bartholomew's, he was sent by Mr. Alcock to the Westminster Hospital.

When the patient first came under the care of Mr. Lynn, the seat of pain was a point of the femur, about six or seven inches below the external trochanter. On the 2nd June last Mr. Lynn had the man removed into the operating theatre, and having laid bare the femur in the proper manner, trepanned the bones, a quantity of pus escaped, and several portions of carious bone were removed. The patient was signally relieved by the operation. The wound healed pretty quickly, and Childs was soon enabled to walk with crutches. His appetite and strength gradually improved, and his habit became fuller. An occasional return of pain in the trochanter, however, throws him back for a time, but upon the whole he is progressing. The wound presents the appearance of a deep sulcus in the direction already described. The integuments are drawn over the sides, and a line of granulating surface is seen at the bottom.

Sept. 2nd.—The wound is not yet cicatrized. The patient's health and strength are much improved.

21st.—He is much better, and walks about with one crutch.

THE UNIVERSITY OF LONDON AND UNIVERSITY COLLEGE.

To the Editor of the Medical Gazette.

SIR,

IN the last page of a detailed prospectus of medical lectures to be delivered in University College, London, there is the following notice:—"Students of this College, as one of the institutions connected by royal charter with the University of London, will be entitled to be examined for Degrees in Arts, and for Honours, Exhibitions, and Scholarships, to be conferred by the Senate of the University, &c." I would ask who has authorized the secretary of University College to hold out to young men the inducement to matriculate at the London University, which is implied in the words, "Exhibitions and Scholarships to be conferred by the Senate of the University?" The London University has no endowments or funds of any kind, and therefore has not either exhibitions or scholarships to confer. The want of truth exhibited in the paragraph I have quoted, has caused in my mind the suspicion that some unworthy motive has induced the directors of University College to issue such a notice, and that it has been done in concert with the advice or by the authority of some member or members of the senate of the London University. I am confirmed in my suspicion by reading a notice referring to the same subject, issued by King's College, which, equally with University College, is "connected by Royal Charter with the University of London." The notice is as follows:—"Attendance at King's College qualifies for a degree in the University of London." How different the terms of this notice! Here is truth.

One object in writing this letter is to call your attention to the subject, in order that medical students may be guarded against the false hopes which the paragraph already alluded to is so calculated to induce. If any parent should prefer University College as a place of education for his son, because he thinks the Professors are eminent in the separate branches of knowledge which they teach, I should not be disposed to find fault with his choice, but let him not do so in the hopes that the youth might be a successful candidate in obtaining a scholarship, which would diminish the expenses of his education.

I have no intention of discussing the conduct of those into whose management the Senate of the London University ap-

pears to have fallen, yet I cannot refrain from adding my opinion to those which have already been given in your journal, of their plan of medical education. The "proposed curriculum of the London University" (as detailed to us in a letter published in your journal for August II, and which letter, signed C. L., is said to be written by a member of the Senate of the University) is not in my opinion an improvement of our present mode of educating physicians and surgeons. It only affords another proof of the erroneous view of education entertained by the framers of medical regulations of which our several medical institutions have already given us proofs. It makes the *teaching of the lecture-room* preferable to the knowledge to be gained in an hospital. The curriculum is, as a writer in your last number says, "but a copy of the regulations of some of the Scotch Universities, in which the *professorial** system is exalted, and the *practical* thought of only as subordinate." One of the worst effects of such a system is the adoption, by the idle student, of "cramming" for an examination, in the place of acquiring sound theoretical and practical knowledge, by observing, comparing, and recording facts, under the teaching of hospital physicians and surgeons.

I have said, however, that my intention is not to *discuss* the medical regulations of the University of London, but to expose the implied want of truth contained in the notice regarding the degrees of the University. Whether the terms of this notice have been framed with a view of inducing young men to matriculate at the University of London, or of increasing the number of pupils at University College, the object in either case is unworthy of corporate bodies of men professing to be learned. Should I succeed in drawing attention to their conduct my object will be gained.—I remain, sir,

Your obedient servant, Δ.

[The name of the writer has been sent to us.]

EXTRACTS FROM FOREIGN JOURNALS.

SIMULTANEOUS DISLOCATION OF BOTH THIGHS.

A SAILOR was sitting astride a plank, when a wave suddenly forced him up under a cross beam, which struck his back violently, while the plank was still between his legs. The poor fellow was

lying on his back, when Dr. Sinogowitz was summoned to his assistance. Both limbs were quite motionless, and evidently much deformed from their natural figure. The thighs were separated the one from the other, and could not be approximated; the trochanters were much lower and less prominent than usual, and the muscles of the hips over them were in a state of extreme tension. The body was bent immovably forwards and downwards upon the thighs, the knees were moderately flexed, and the toes were not turned either inwards or outwards. The diagnosis, therefore, was, that the heads of both of the thigh bones were dislocated downwards and inwards. The reduction was effected in the following manner:—The pelvis being secured by two assistants, the surgeon took his place between the limbs of the patient, and having put a towel round the right thigh above the knee, he passed the noose of it over his own neck. Extension was then made by means of a towel made fast above the ankle, and inclined a little to the left side, and while this was steadily continued, Dr. S. lifted the head of the bone, and directed it upwards and somewhat outwards, by raising and stretching out his head with all his power. It slipped into the socket without any noise. The limb was then reduced in nearly a similar manner. The mobility of the limbs was almost immediately restored, at least in the horizontal position; but several months elapsed before the patient could walk with any degree of ease. The tediousness of the recovery was owing, in a very great measure, to the severe injury of the lumbar vertebrae, which he sustained at the time of the accident. For three weeks, the sphincters of the bladder and rectum were quite paralyzed. — *Preussische Medicin. Zeitung.*

ANIMALCULES DEVELOPED IN PUTREFACTION.

At a recent sitting of the Institute, MM. Beaupérthuy and de Roseville presented a memoir of microscopic animalcules as a cause of putrefaction. The results to which their investigations lead them are as follows:—When an animal substance is placed in circumstances favourable to putrefaction, one sees after a certain time (varying according to the temperature, and hygrometric state of the atmosphere) animalcules formed, and this before any faint odour has been developed, and even before the material presents any indication of an acid or alkaline property. These animalcules, which have at first the form of monads, then that of vibriones, are nourished at the expense of the substance in which they are developed, and multiply

* The word "*professional*" is, I presume, a printer's error. [Probably it ought to have been "*theoretical*."]—ED. GAZ.]

LECTURES ON SURGERY,

DELIVERED AT ST. THOMAS'S
HOSPITAL,

BY THE LATE MR. CLINE;

With Notes.

[THESE lectures were written by Dr. Wilkinson when attending Mr. Cline's lectures, in the years 1787-88-89.

Extract of a letter from Dr. Wilkinson, dated Feb. 6, 1838:—"They (these lectures) are the results of six courses of lectures I attended at St. Thomas's, in 1787, 1788, and 1789; and I am in hopes I did not omit any interesting part of Mr. Cline's valuable observations. The one I had the pleasure of giving you is the repeatedly corrected copy."]

LECTURE II.

Operation for Hare-lip—Exstirpation of the Tonsils—Elongation of the Uvula—Hemorrhoids—Polypus of the Uterus—Polypus of the Nose—Bronchotomy—Wry Neck.

Hare-lip.—The lip is so called when there is a fissure dividing it into two. It is only in the upper lip where such fissure occurs. Sometimes there are two fissures—then called a double hare-lip; one is situated on each side. Not unfrequently in such cases, the fissure is not confined to the lip alone, but is likewise extended through the bones, making a fissure in the maxilla superior, extending through that bone, the palatine process, likewise the os palati, leaving a communication between the mouth and nose, so that the child when it swallows has part of the fluid escaping through the nostrils. Sometimes children are born with such a defect of the velum palati, without the bones or lip being concerned: sometimes

the bony palate is affected without the lip or velum palati. It is the fissure in the lip only that is curable by an operation*; but the division in the bone may be remedied by an artificial palate. The instrument-makers fasten a bit of cork on a small plate of silver adapted to the size of the division of the bone; on the cork is a piece of sponge, which passes upwards into the nose, and keeps the plate supported, whilst it is as easily removed and cleaned from time to time. This is of great use to the patient, who is hence capable of swallowing better, and speaking more distinctly. But this instrument should not be introduced in a growing child, because it might tend to enlarge the opening.

In the hare-lip the edges should be pared, occasioning a raw surface; by bringing them in contact union will be produced, whereby the deformity without can be remedied. This cannot be performed at all times, as when a child is sucking, for it will be incapable of sucking till after the wound is healed, thus obliging us to wean the child at an early period. Therefore it is better to perform the operation after the child has done sucking. Many object to its being performed before the age of five years; however, it has been frequently performed with success before that time. It is a simple operation, and used to be done with a pair of scissors, which, however, rather pinch than cut, which is more unfavourable for the cure†, therefore a knife is preferable; or, what is perhaps still better, a lancet. Before the edges are pared, the lips should be raised from the

* The experience of late years has shown that the fissures of the palate are remediable likewise by operation.—C.

† Mr. Lawrence and other distinguished surgeons recommend the scissors *with knife edges*, as being particularly convenient in this operation, for they cut with great facility, and do not bruise the parts.—C.

gun. By holding up the lip, and dividing the membranous connexion, you have a greater command; in doing this, it is necessary to introduce a piece of pasteboard underneath. If the operation be performed with a lancet, which is preferable, from its cutting with such great ease, you thrust it through, and draw it up quite to the angle; as little as possible should be cut, the making a raw surface being all that is necessary; the more you cut off the greater will be the difficulty of bringing the parts into contact. To confine the edges pins are used, which may be either silver or gold; if silver, they should have steel points, which may be taken off. When gold, they are sharp enough without having any part to take off. Three pins are commonly used, but two are quite enough; these are to be passed through, from the outside of the inner edge of the lip, then out on the opposite side; bringing the parts in contact, you introduce the first pin near the edge or villous surface, but not in the part where it is most vascular. The second pin is to be introduced midway between the first pin and upper edge or angle of the division. We then pass the ligature round each pin, to keep the edges together in the form of an 8. The points of the pins, if steel, should be removed; if gold, some wax may be put on the points, to prevent their irritating the lips, over which some sticking-plaster may be applied. Authors differ very much respecting the time that pins should be retained. Le Dran says they should be taken out in a few hours, while many contend they should be left in for ten days. It is very certain that in forty-eight hours a tolerably firm union will be produced, and in many cases they may be safely removed; but in others if removed in so short a time, a separation will take place. This happened to me once on the fifth day after the operation. The union may be produced by the common interrupted suture, which I think is equal, and lying softer on the parts is not productive of so much pain as where there are pins. In either case, the necessity of leaving the pins or ligature will be the same. In an instance in which I performed it on a child two years of age, the gentleman who attended with me removed the ligatures on the second day, when very good union seemed to be produced; it remained in this state during some time, when the child was seized with a fit of crying, during which the wound again opened, not completely, but about one-third from the edge; this was attended with some deformity, but gradually wore off, as the child grew up. Another case occurred to Mr. Else; on the third day after the

operation, he took the pins out, the child instantly began to cry violently, and completely separated the edges of the wound. In all these cases, where the child is so young as to be in danger of separation taking place, it would be better to keep in the ligatures six or seven days; but in an adult who has command of himself they may be removed on the second or third day. In those cases where there is more than one fissure, the process should be performed at twice, letting the first get well before performing the operation on the other; to operate on both sides at once, will be productive of great inflammation, and will be putting the parts so much on the stretch, that you will be less likely to succeed. When there is a double fissure through the lips, and likewise through the jaw, a considerable projection takes place, probably from the lip being divided in that manner, and not restraining the growth of the parts, of course the upper jaw is more projecting than the under; there have been instances where the four incisors of the upper jaw have been quite projected over the under lip. The difficulty in the cure will here be great on account of the prominence over which you are to bring the divided lip. Where the jaw is considerably projected, it would be right to remove a portion. This was done some time ago on a child in this hospital by Mr. Girle. He took off the projecting portion of the four incisors with a pair of pincers; on removing it a considerable hæmorrhage took place, probably from the palatine branch of the internal maxillary artery. To stop this hæmorrhage, and be able to bring the middle portion of the lip in contact again, one of the pins with which he performed the operation, was passed through the lip and through the bone; this stopped the hæmorrhage, and produced union between the lip and divided bone. Mr. Else said his case got well with but very little deformity, and which did not appear when the mouth was shut. There have been bandages contrived for performing this operation without the use of pins and ligatures, of which there is a very ingenious one invented by Mr. Dent, of Ireland—a kind of uniting bandage; this cannot be depended upon at first, but may be very conveniently used in many instances after the removal of the pins or ligatures, as a further support, and to prevent suppuration.

Excision of the tonsils.—The tonsils sometimes become extraordinarily enlarged from a diseased state, and produce such inconvenience as to require their removal. They are very subject to inflammation. When inflammation is taking place about the throat, these are generally

more inflamed than the contiguous parts; they seem to be particularly susceptible of disease. The same occurs in the venereal disease—the greater number of ulcers are in the tonsils. In those cases, where they become inflamed in consequence of cold, they often become very much enlarged, and one projects towards the other, sometimes so considerably, that they meet, filling up the fauces, stopping deglutition, and producing great difficulty of respiration, being situated so near the epiglottis. In such cases their size should be reduced as speedily as possible, which may sometimes be effected by the antiphlogistic regimen and blisters in the neighbourhood of the part, as behind the ears, neck, &c. But when there is urgent necessity, as where the increased size of the tonsils is so rapid as to endanger suffocation, it is advisable to scarify them, making a few small punctures on the part, which being vascular, they soon become less, from the immediate hæmorrhage which follows. This will sometimes be better effected by strewing some crude sal ammoniac* on the surface of the gland, which almost immediately produces a slight excoriation and hæmorrhage from the parts, with almost immediate relief. Sometimes the tonsils will go on to suppuration, though very rarely; when it is so, the pus should be evacuated by a puncture. Some persons are very subject to such inflammations, for in many instances of those who have had their tonsils once inflamed from a very slight cold, are subject to have them inflamed again; the consequence of which is, that at last they remain in an enlarged state; after the inflammation is abated, they do not return to their former size, so that the patient has a thick speech, as if there was something at the posterior part of the mouth. This enlargement will remain in an indolent state, and often cannot be removed by any application: indeed sometimes the enlargement and hardness are so great as to require an operation. When the tonsils are in this enlarged and indolent state, independent of actual inflammation, they are generally called *seirrhus*, not that they are of a cancerous tendency,—indeed I never saw a cancerous tonsil; you are seldom able to remove them entirely, still they do not return, which they would do if of a cancerous nature. Their removal used to be effected by excision; but this is usually attended with a considerable hæmorrhage, being a very vascular part, hence difficult to restrain. It has been found necessary to use the actual cautery

to effect it; to prevent which, some have torn them away with very strong forceps; this is a very cruel violent operation, and very dangerous; for you are not sure of removing the tonsil alone, but may remove some important contiguous part at the same time; therefore, both these modes are improper.

Mr. Cheselden has contrived a very ingenious instrument for tying the tonsils—a tonsil probe, which is an eyed probe in a handle, threaded with a double ligature; also an iron with an eye at each end, for the purpose of fastening the ligature. This probe is intended to carry the ligature under the basis of the tonsil; you pass it into the mouth over the tonsil, then bring out the probe, and you have the ends of the ligature out of the mouth, and the thread itself around the root of the tonsil: upon this make a common knot, and as it is out of your reach to command the ligature with your fingers, the tonsil instrument is to be used; one end of the ligature is to be passed through the eye of the instrument, which being passed down and thrust beyond the tonsil, and the other end being drawn towards you, a firm knot may be made. In the same manner you make a second knot, and carry the instrument as before into the mouth, thrust one end from you and draw the other to you, then cut it pretty close. Thus, a ligature being tied on the root of the tonsil and around it, will form a groove, so that there will be no danger of its being separated. This ligature will not be sufficient to stop all circulation through the tonsil, the basis is of such breadth; it will become inflamed by this pressure, and somewhat enlarged, and ulceration will take place where the ligature was applied. You then apply a second ligature in the same manner, drawing it as tight as you can: this will stop all circulation, the part will die and fall off; repeating the ligatures if necessary.

Mr. Russel, of Worcester, ties the tonsil without any probe, which he has practised for many years, in which he is very dexterous, having long fingers. When you can make use of a finger, it is always preferable to any instrument. We every now and then have tonsils whose bases are so broad and tapering towards their extremity, that you cannot fix a ligature on the base. Under such circumstances a single ligature is not sufficient. Mr. Cheselden has contrived a tonsil needle, threaded with two ligatures, one of which is coloured, that we may distinguish them from each other; this should be introduced into the mouth to the further side of the basis of the tonsil. When the eye of the needle is passed through, we get hold of the ligature with a common dissecting hook, bringing it out at the mouth; then you keep it fixed and withdraw the

* Sir A. Cooper recommends the application of the nitrate of silver, or sulphate of copper, in these cases.—C.

needle. One of the ligatures is to be tied over one half, and the other around the other half, as before directed, with the tonsil iron. The needle should be much bent. This operation is tedious and embarrassing, from the great irritability of the parts; and the increased secretion excites the patient continually to cough. In this way the whole of the basis of the tonsil is inclosed; the ligature should be cut off short; if left long it gets into the pharynx, and there produces irritation. This is a very convenient way of performing the operation, as it prevents the ligatures slipping; and they make such an impression on the basis, that you may easily apply a second ligature when single ones will be sufficient. The only difficulty is in getting the needle through.

A ligature is thus to be repeated till the tonsil falls off. This is a case in which this kind of treatment is attended with very good effect, as there being no cancerous tendency in the part the patient finds no inconvenience afterwards. Mr. Warner gives a case, in his *Surgery*, of a tonsil he removed by excision, attended with a hæmorrhage, which he stopped by astringent gargles. It is not only the tonsils we remove in this way, but various other tumors, which are necessary to be removed, where instruments of the same construction, though varied according to the size of the parts, are very useful, as excrescences in the rectum, &c.

Extirpation of the uvula.—This sometimes becomes necessary from a diseased elongation of the part. In persons who are very subject to inflammation about the throat, the uvula partakes of it, becomes enlarged, and elongates; from which state it does not return to its former size. Stimulants applied to the part will sometimes occasion it to relax, at others it will resist all stimuli. The elongated uvula irritates the glottis, produces coughing, or sometimes tickles the pharynx and excites vomiting. When this is recent, it will frequently contract on the application of astringents; if not, a part of it should be removed, which is a very simple operation. Introduce a pair of scissors upon a long pair of forceps which has previously hold of the uvula; then take off as much as is preternaturally elongated. A very inconsiderable hæmorrhage follows, and the patient will be well in a few days: if troublesome, an astringent gargle may be made use of.

Piles.—These consist of varicose enlargements of the internal hæmorrhoidal veins; sometimes there is a diseased thickening of their coats, forming a hard tumor. They are sometimes so large, and have been of so long continuance, that it is impossible to remove them by medicine, or any external

application. When they are large, and occupy a large portion of the inferior part of the rectum, this is thrust downward, producing a prolapsus, attended with pain, at every attempt to void the feces. Patients in this state are very apt to become worse from being costive. The frequent desire to go to stool, if possible, from the pain it produces, increases the size of the piles, and this again accumulates the hard feces; they are with great difficulty passed through the rectum. Therefore such patients should particularly guard against costiveness. But when in this enlarged state, and medicines prove of no use, they should be removed. This was formerly done by excision, which is now laid aside, from the hæmorrhage which follows; therefore, ligaments are preferred, which is very convenient when the rectum protrudes readily. For this purpose the patient may be directed, before the operation, to sit over the steam of warm water, and to strain as if at stool, whereby the rectum may be forced down. If there are several they should not be tied at once, as the patient could not support the pain and inflammation, two or three at a time being generally sufficient; this done, the rectum should be returned; if left out it would soon become in a strangulated state, inflammation increasing its size. The ligatures are left on till they fall off spontaneously. These tumors are so small, that you may readily compress them, so as to prevent any circulation through them. After the first are removed, and the inflammation subdued, you may tie two or three more; and repeat this till they are all extirpated. After this the patient voids his feces with more ease, and without producing prolapsus ani, which, however, is not always the consequence of piles, and then they are not so easily removed. In this case the piles are situated in the internal surface of the rectum, and then it will be necessary to secure them somewhat in the same manner as the tonsil; the same holds good if any scirrhus tumors are formed in the inside of the lower bowel. Mr. Else had a patient once with several of these tumors, situated in the rectum about as high as the fingers could reach, rather higher than could be commanded by any instrument; he was therefore obliged to cut through the sphincter ani, and was further assisted by the speculum ani, which is very convenient when any operation is necessary in the rectum, as it gives you a better command of the part. After dilating the rectum a little posteriorly, he was enabled to tie them. They soon fell off, and the patient, from suffering constant and extreme pain, became immediately easy, which, however, did not continue long; for after six or

eight months the pain and tumors returned, and the rectum soon became in a cancerous state, which destroyed the patient. In this case, probably, if the patient had submitted at an earlier period, he might have been cured; but the parts below being diseased, endangered a return of the complaint.

This operation may also be performed to remove—

Polypi uteri.—These often extend through the os tincae, and grow so large as to project through the os externum, which produces considerable pressure on the contiguous parts, from their dilating the vagina, of course attended with pain and great inconvenience to the patient, therefore they should be removed, which is most conveniently done by the instruments above described. These polypi uteri project through the vagina, when they can be distinctly felt by the finger, and may be safely tied; but we should be very careful that we are tying the polypus, and that only; for if any of the uterus is included, the patient's life is in the greatest danger. These polypi have, in general, narrow bases. When you can distinguish the os tincae, you make use of

this instrument, contrived by Dr. Hunter, a kind of tonsil iron, curved a little, and fixed in a handle with two shoulders, or lateral projections near its extremity. (See preceding figure.) You pass both ends of the ligature through this, then carry it down to the basis of the tumor; the ends of the ligature are to be brought over the shoulder on each side of handle, and tied by a slip knot, leaving in the instrument. The great advantage of this instrument is, the ease with which you can increase the pressure at different times. Every day draw the ligature as tight as you can, till it has made its way through the polypus, taking particular care that you include nothing else, which you may be pretty sure of if it gives no pain, a polypus not being a sensible part; whereas, if the patient complains of pain, you may be sure some other part is included. We should at first, in all such cases, ascertain the extent of the disease before the ligature is attempted.

Polypus of the nose.—The polypus that forms in the nose originates from the mucous membrane, where there is frequently a soft excrescence of a cream-like colour, very much like the appearance of mucus. When these increase considerably in size, they are sometimes situated forward in the nostrils, sometimes backward in the pharynx. The nose externally becomes enlarged, and the bone is altered in form: it obstructs respiration, and occasions an alteration of voice. The operation is very simple, and consists in getting hold of the polypus as near the root as possible, for it is so tender as to be easily torn through, and if you do not take it out by its root, you will only give slight relief to the patient. If you can introduce the finger it will be the most convenient instrument, by which you may force it off; at the same time you will be assisted by getting hold of the polypus with a pair of forceps; then you will be able to command it better than with the forceps only. The French direct ligatures to be made on the polypi for their removal. In this way they are not so completely removed as by extraction; therefore the patient would be liable to return of the complaint. A ligature being made on the part may assist in some degree in bringing it forward. When the polypus is very large, and projects backwards into the pharynx, so that it cannot be drawn through the nostrils, it will be better to get hold of it with a pair of curved forceps, introduced under the velum palati, drawing it downwards and a little backwards. The curved forceps is also necessary where a polypus is situated far back in the nose, for straight ones may pass over it. Their re-

moval is generally attended with a moderate hæmorrhage, for which some dossils of lint, applied so as to make pressure on the part, will be sufficient; and if threads are tied to them they will be more easily removed. Sometimes the polypus adheres to the bone, a small portion of which coming away is favourable; after which it is less liable to return. There is sometimes such a disposition throughout the membrane to form polypi, that they grow again as fast as they are removed. There is besides another enlargement of the membrane, also called a polypus, but very different in form: in this a thickening of the membrane takes place, putting on a dark purple-coloured appearance. This is generally of a cancerous nature, mostly attended with pain; and when you extract it you only increase the disease. This will also destroy the patient sooner or later, for, being of a cancerous nature, it goes on increasing. It ought to be carefully distinguished from the other, and should not be meddled with, as it only exasperates the disease.

Bronchotomy.—This operation consists in making an opening into the trachea for the purpose of respiration. This is sometimes necessary to prevent suffocation taking place. Various causes may make this requisite; as extraneous substances getting in to the upper part of the larynx and sticking between the ligaments of the glottis, will produce almost immediate suffocation, if not instantly coughed up; and the food going the wrong way may be so wedged in that it is impossible to cough it up; of which there was an instance in this hospital in one of the nurses, who, while she was eating some beef, suddenly fell down from her chair and expired: it was found that the piece had stuck in the upper part of the larynx. From the epiglottis not performing its office, any aliment may get in, as happens with respect to fluids, in laughing, &c. Another instance was that of a beggar, who, while asking alms in the street, having food in his mouth at the time, suddenly fell down and expired: one of the resurrection-men passing that way, mixed with the crowd, and, seeing the man dead, thought it a good opportunity to come at a body, so he claimed the beggar as one of his relations, and took him in a coach to the hospital! On dissection, a piece of cabbage-stalk was found in the trachea, for he was eating cabbage at the time. In this instance there was a destruction of the epiglottis by exulceration. Fluids are incapable of obstructing respiration, but solid food getting into the trachea will endanger suffocation. In either of the above cases, had an opening been made into the trachea, respiration would have gone on by the opening, and life would have

been saved. Suffocation may also happen from other causes, as tumors situated in the neighbourhood of the trachea, or matter between the larynx and pharynx, inflammation taking place in the larynx occasioning a thickening of the mucous membrane, so as to prevent respiration going on in that part of the tube; therefore, in the disease called the *croup* in Scotland, which we now and then see in this country, when, from inflammation of the air-tube, a quantity of coagulable lymph is thrown forth, which sometimes so obstructs the aperture as to produce suffocation, from which children frequently die: in either of these cases, where there is a danger of suffocation, an opening should be immediately made into the trachea; as it is a well-known fact that a mere wound in the trachea is of no consequence. This is a very simple operation, and may be done with any instrument. The manner of performing it is by making a longitudinal incision from the cricoid cartilage down on the fore part of the trachea. The cricoid cartilage is very readily distinguished by the feel. Laying the larynx bare, you will next cut between the cartilages, if you can; but if you divide them it is immaterial. The patient's head should be inclined forwards, to prevent blood getting into the air-tube, which it would irritate considerably. Even common air has this effect in a catarrh. We are directed to introduce a silver cannula* for the patient to breathe through, but I much doubt whether it ever was or ever can be used; for the internal membrane of the trachea is an exceedingly sensible part, where, from the introduction of any extraneous body, such a violent degree of coughing would be produced as to be intolerable to the patient. Besides, if the opening is large enough, a cannula will be unnecessary. If no more injury is done than wounding the trachea, the patient frequently gets well; therefore, in such cases, it will be better not to use any cannula, but merely to make the opening large enough. Apply no dressings, only a piece of gauze over the part, through which the patient may breathe. This operation was performed on a child, dying of the croup, by Mr. Andrée, by making an incision into the trachea, with success. When extraneous substances get into the larynx, endangering suffocation, if a surgeon is present, it would be proper to take a knife or lancet and open the trachea. Even if the patient has done struggling, by blowing air into the

* In many instances where bronchotomy is required, the introduction of a silver cannula is found to be absolutely necessary; and although in some cases much irritation is produced, yet in others it is borne with very trifling inconvenience. — C.

lungs, after making an opening, respiration would return, and the patient might be saved, in the same way as with persons who have been apparently drowned or otherwise suffocated; by inflating the lungs, respiration is again produced. When I was first at this hospital, a man died here in the passage, from a glandular tumor situated in the throat. He had been in the house for some time, and used to breathe with extreme difficulty. One day, while I was dressing some patients in the ward, he was making a great noise, and all of a sudden fell down; and after a few struggles expired. Had bronchotomy been performed, he might probably have been saved.

Wry neck.—Now and then, from a diseased contraction of the sterno-cleido-mastoideus muscles, the neck is turned on one side, and kept immovably fixed; the muscle becomes rigid, entirely losing its ductility. Its fibres lose their capability of elongating, and the whole muscle becomes in the same state as a tendon. While this disease is forming, the muscle gradually shortens and throws the head on one side, in which state it remains. Where the complaint affects the mastoid only, it may be removed by dividing the muscle. If the contraction has taken place at an early period in life, probably the bones will have undergone such an alteration in their form, that dividing the muscle merely will not remove the complaint. However, if the growth is not complete, there is a chance of recovery by the child using a machine to keep the head upright, and the bones undergo such an alteration that the natural position of the head may be restored. This operation consists in laying the mastoid muscle bare, near to its origin. Some have directed it to be divided in the middle, but here it is improper, on account of the situation of the carotid artery, which is there passing very close to the muscle; therefore it is better to divide it near its origin. The incision is made a little above the clavicle, in the direction of that bone; laying bare the muscle under which the syringotome, or probe razor, is introduced, by drawing of which through, the muscle is divided. Some lint should be introduced, and the head kept in a proper position, or confined by bandage. Mr. Gooch, in his Surgery, gives a case where a similar deformity was produced by a contraction of the platysma myoides, which he divided with a knife, and the patient perfectly recovered. Other muscles may be divided for the same reason, as the biceps flexor cubiti; but to divide the brachialis internus would be improper, on account of the situation of the brachial artery. The mastoideus

may safely be divided, by dissecting through it carefully without the syringotome. In all these cases we should examine carefully whether it is the muscle only which is producing the deformity, otherwise we shall be frustrated.

CLINICAL LECTURES ON MEDICINE,

Delivered at the Meath Hospital, Dublin,

Session 1837-8,

BY PROFESSOR GRAVES.

INTRODUCTORY LECTURE.

TO-DAY, gentlemen, we commence our labours for the winter session. I hope you will manifest a steady and sustained diligence in your hospital attendance, observe carefully the various forms of disease submitted to your inspection, and accurately note the symptoms, together with the effects of the remedial measures. As usual, I have allotted the cases at present under our management to the more advanced students; it is their duty to take charge of each, and write on a folio sheet of paper (which is pinned to a large card suspended over the patient's bed) its previous history and existing symptoms; thus recording its progress and treatment from day to day. In a former lecture, published in the *MEDICAL GAZETTE*, I endeavoured to explain the advantages of this system; at present, therefore, without entering into its details, I shall content myself with remarking that we have had many years' experience of its beneficial effects in the Meath Hospital, where this, the German mode of clinical instruction, was introduced by myself in 1821; I must remind you, however, that even its utility is necessarily proportioned to the diligence of the student. There is no system capable of communicating information to the indolent; every man must depend chiefly on his own assiduity, and all the teacher can do is to facilitate the means of acquiring knowledge, and afford an example of punctuality and attention. I would seriously recommend every one who undertakes the management of cases, to set out with a fixed determination to persevere throughout the whole session. Few things give me more concern than to find young men, who have commenced with ardour, becoming by degrees less and less industrious, until their hospital attendance degenerates into an irksome task, imperfectly performed, and at last wholly neglected. One of the most valuable things which the student can acquire is, a habit of daily diligence. The knowledge requisite for the efficient

discharge of our professional duties is not to be acquired by sudden starts of intense application, or by the overwrought strivings of desultory exertion; it demands a daily and hourly attention, a steady, constant, and accurate course of observation, continued uninterruptedly for years.

I think students are very much misled as to the best mode of becoming good practitioners. This is an age of ambitious acquirement, and professional men seem to be ashamed unless they have the character of universal knowledge. Every body studies everything, and the consequence is that few know any thing well. We live amidst the din of declamations in favour of general education; and are every where assailed by the ceaseless competition of those who vend cheap knowledge in the form of penny periodicals, lectures innumerable, and hosts of rival encyclopædias; but ours is not an age of calm unpretending acquirement, and severe precise study, without which the effort to become good physicians and surgeons must prove vain and fruitless. Can any thing be more embarrassing than the multitudinous array of studies presented to the young student, who comes to London or Dublin with the view of educating himself as a general practitioner? So many departments of knowledge are spread before him, and so numerous are the exhortations to study each with particular care, that he feels at a loss where to begin. The merits, advantages, and necessity of his own branch, are insisted on by the respective teachers, with all the force of impressive eloquence; and after running the round of introductory lectures, (an initiatory penance duly performed by all beginners,) he returns in the evening to his home puzzled and dispirited. He finds that it will be necessary for him to become an excellent botanist, an able and scientific chemist, and a profound anatomist; that he must have some knowledge of zoology, be well versed in comparative anatomy, know how to detect poisons with accuracy, and study the legislative enactments which bear on questions of medical jurisprudence. Physiology, materia medica, therapeutics, nosology, morbid anatomy, the principles and practice of surgery, medicine, and midwifery, claim, all and each, his especial attention; nay, many teachers insist upon the necessity of his becoming master of several languages—Greek, Latin, French, and German; while others assure him that he never can prosecute scientific medicine with success unless he studies physics as well as physie; some there are even who encourage him to cultivate mineralogy and geology, as if forsooth a knowledge of these sciences could teach the laws that regulate diseased action, or

the indications which should govern the exhibition of remedies. In a lecture lately published by my friend Mr. Hayden, I find it remarked "that to keep pace with the modern race of intellect, we should get on a railroad of literature; mathematics, natural philosophy, the art of drawing, and above all, logic, will be indispensable." Dr. Elliotson would no doubt add metaphysics, animal magnetism, and phrenology, sciences he has cultivated with success, and taught with perspicuity! Dr. Latham, who has had sufficient courage to put forward his opinions on this subject, has demonstrated, with much truth and force, the injustice and folly of attempting to impose so many burthens on the minds of students, and has shewn clearly the bad consequences resulting from such a mode of proceeding. No profession requires a sounder preliminary education than ours, and in none ought education to be more studiously directed to promote the activity and development of the mental powers, especially those connected with the habit of observation as well as with the judgment and memory. The latter faculty should be cultivated from the earliest period, and the boy should be taught the chief anatomical names, as those of the different parts of the muscular, nervous, and vascular systems, which names he will of course find no difficulty in retaining when a man, and it will then only be necessary to learn the qualities of the things to which they belong. If, in addition to this, boys were taught the scientific names of the chief articles of the *materia medica*, and the technical terms and classifications of botany and chemistry, much trouble would be saved them in after life; and their memories, while in the state of greatest activity, would be much better employed than in attaining the rules and terms of syntax, prosody, mythology, and ancient geography. I would not recommend any one to commence the actual study of medicine and surgery until the age of nineteen. Before that period the mind is not sufficiently ripe for practical observation, nor sufficiently stored with that knowledge (only to be gained by the daily intercourse of life) which teaches us to estimate the effects of moral or physical causes on the human system, imparts to us the power of weighing conflicting evidence, and detecting the too frequently incorrect and erroneous statements of our patients. A certain knowledge of the world is indispensable to the physician; and it is only loss of time—yes, of precious time—to employ boys in trying to learn what can only be acquired by men. Those who attend hospitals at too early an age are very apt to acquire careless habits of observation;

all the interest which disease presents, when observed for the first time by matured minds, is lost to them, and all the attraction of novelty has ceased long before they possess that tact and experience which enable the adult to understand the meaning of symptoms, the progress and phases of morbid phenomena, and the effects of therapeutic agents.

It is then the duty of parents, guardians, teachers, and all who superintend the education of youth, to see that those who are destined for the medical profession should have their minds prepared and strengthened by diligent cultivation during early youth, not only by the attainment of extra professional knowledge suited to their means and opportunities, but also by instruction in those portions of anatomy, *materia medica*, botany, and chemistry, which may be readily comprehended at that age. Especial care should be taken to impart to them some knowledge of the physical qualities of medicinal substances. All this being done, when the student, arrived at maturer years, comes to grapple with the practical departments of his profession, he will find many difficulties easily surmounted, and at this period he should disengage himself from too devoted an attention to the accessory sciences. But he need not wholly detach himself from them; some one of them may be cultivated along with his more serious pursuits. He may devote one session to lectures on chemistry, another to those on botany, a third to physiology, and so on of the rest. But his main object must now be the acquisition of practical knowledge, and consequently the greater portion of his time and energies must be devoted to the clinical wards and dissecting-room of an hospital, to the study of the *materia medica* and pharmacy in an apothecary's shop, and to practical anatomy. Five or six years' attendance on an hospital will be little enough to qualify you to enter with propriety and confidence on the discharge of your professional duties. Bear in mind, gentlemen, that when you come to treat disease, you approach the bedside as physicians or surgeons, and not as chemists, botanists, or anatomists. This is the character in which you are to appear; and, to the acquisition of knowledge which will prepare you for the discharge of its duties, you ought to engage your chief attention.

Some of you, gentlemen, may think that it ill becomes a teacher to narrow the limits of your exertions, or circumscribe your pursuits. But let me be understood. What I wish to impress upon your attention is, that you ought to address yourselves mainly to the acquirement of what is really useful, and should store up chiefly

what is most important and available. And in furtherance of this object I think it my duty to warn you against the well-meaning but injudicious representations of those who would turn you from the study of practical matters to the cultivation of their favourite sciences—sciences connected with and ancillary to medicine, but in which medical students are too often encouraged to engage with an ardour that indirectly, but certainly leads to a less zealous and efficient attention to more important matters. Take, for instance, two of the most popular of the adjunct sciences—two usually regarded as most intimately connected with the study of medicine, botany and chemistry. Both are extremely valuable in themselves, and a certain acquaintance with them is undoubtedly desirable; but to the student in medicine their utility has been greatly overrated. Botany is an extremely interesting and useful science; but I believe you might be very good practitioners without knowing the classes of Linnaeus, or the families of Jussieu. To be sure, if you had the misfortune to practise in localities separated from the ordinary channels of commerce; if you were suddenly bereft of the numerous stores which maritime enterprise pours into the lap of medicine, and obliged, like the herbalists of old, to search the woods and fields for your *materia medica*, you would certainly be often at a loss, and might make some serious mistakes, unless you were adepts in practical botany. But this labour, fortunately for us and for every European practitioner, is quite unnecessary. A small capital will bring the vegetable productions of the most distant countries to your door; and any respectable druggist will for a trifling sum provide you with all the medical substances derived from plants, carefully selected and accurately prepared.

Those who boast the most loudly of their acquisitions in botany, and who lay most stress on its importance, know very well that to the physician it is of little or no practical value. Take one of the best of our English or Irish botanists, and see how meagre a knowledge he possesses after all, of many of the plants whose products are employed so largely every day in the treatment of disease. Transport him suddenly to the East or West Indies, to Africa, or South America, ask him to shew you the camphor or the cinnamon-tree, the cajuput, the croton, or the guaiacum,—I doubt very much whether he would be able to recognise logwood, or even ipecacuanha, growing in their natural situations. Again, there are a great many vegetable productions used every hour in medicine, of which it may be said, that no two botanists are agreed as to the precise

description of plant from which they are derived. There is no substance in such common use as gum Arabic, and yet, notwithstanding all that has been written on the subject, it is not clear from what particular plant it is derived. Nor do I think it necessary to know whether the gum we use in compounding a cough medicine comes from the *Acacia vera* or *Acacia Arabica*. In like manner, the plants which furnish arrow-root and many other substances in common use are by no means determined. How many disputes have there been with respect to the genus *Cinchona*? And what has been the result of all our investigations concerning the plant which produces this great remedy. Listen to what my late learned friend Andrew Duncan says, in the Supplement to the Dispensatory: "Notwithstanding that all the British colleges agree as to the botanical species of *cinchona* from which the commercial varieties of bark are derived, there is no satisfactory evidence that they are right; on the contrary it is almost certain that in regard to some of them they are wrong." How many years were *columba* and many other similar productions employed before scientific botanists knew any thing of their true history? In 1829 a paper was read, by Dr. Hancock, on the tree which yields the *Angustura* bark; it appears that even Bonpland and Humboldt had described the wrong tree, and consequently it has been called for many years a *Bonplandia*; whereas it belongs, it now appears, to another genus, named *Galipea*: it is not a majestic forest tree, eighty feet high, but a very humble plant, half tree half shrub. Dr. Hancock has also proved that the *Smilax syphilitica* of Willdenow is not the true sarsaparilla, which, consequently is produced by a plant not yet described; and at what conclusion does Dr. Hancock, who spent many years in South America, arrive? Why that the only criterion for knowing good sarsaparilla is its taste when chewed! In proof of the uncertainty which still prevails concerning the determination of species used in medicine, I have only to refer you to the admirable lectures of Mr. Pereira in the *MEDICAL GAZETTE*, and those of Dr. Sigmond published in the *Lancet*.

I do not wish to undervalue botany as a part of general education. Few sciences are more attractive, and few are more likely to become an object of enthusiastic pursuit; but it is the very enthusiasm it is so likely to generate that I wish to warn you against. Botany is an excellent exercise for the minds of youth: it gives habits of accuracy of observation, and tends to strengthen the memory. It leads to healthy occupation, and affords a source

of innocent enjoyment. As productive of so much good, let it form a part of the early education of young persons in general; sure I am that its cultivation would give a healthier tone to both mind and body, than are to be obtained from many of the studies with which boys are now tortured in the schools. But let botany be restricted within its proper limits; and when once young men have seriously engaged in the acquirement of medical and surgical knowledge, let them not entertain the ambition of becoming accomplished botanists.

Speaking of botany I may observe that it is much to be regretted that the names of plants should undergo so many mutations. What was formerly called *Stilobium* has successively become *Dolichos* and *Mucuna*; while Iceland moss has been changed from *Lichen* into *Cetraria*, and *Secale cornutum* into *Acinula clavus*. *Uva ursi* is now preceded by the prænomén *Arctostaphylos*; and our old acquaintance *jalap*, deprived of its euphonious prefix *Convolvulus*, has degenerated into *Ipomæa*. All these changes are useless or injurious, and entail as a necessary consequence, that the young, the middle aged, and the advanced in life, use a different medical vocabulary. The *materia medica*, too, as now taught by scientific professors, presents a serious stumbling-block to students. Teachers do not confine themselves to shewing the different drugs and preparations, but they enter into very minute details of their natural history and characters; so that the student cannot learn the properties of bees' wax without being entangled in the difficulties of entomology, or the nature of isinglass without learning the hard names used in ichthyological classification.

The same observations apply to chemistry. It is a science fully as attractive as botany, and medical men are apt to spend too much time in its pursuit. Some very pertinent observations on this subject were made in the *MEDICAL GAZETTE* about five or six weeks ago, to which I refer you: they are conceived in a spirit of good sense and sound judgment, and you will find them well worthy of an attentive perusal. I grant it may appear very like a paradox to say, that you need not know much practical chemistry. But if you go to a reputable druggist with money in your pocket, he will furnish you with all the chemicals you have need of, excellent in their kind, and prepared with scrupulous exactness. You will get good calomel, good sulphate of quinine, and good hydriodate of potass. So far as chemicals are required for medicinal uses, you can have them all of the best description. But it will be said, that without

an accurate and extensive knowledge of chemistry you cannot prescribe. This is an assertion to which I cannot assent. A very limited knowledge indeed of chemistry will enable you to ascertain what substances are compatible with each other, and a small share of attention will prevent you from making any important mistakes. Besides, you are all aware that many of our best prescriptions contain incompatible ingredients; and that many compounds which would be sneered at by the mere chemist, as heterogeneous and absurd, prove decidedly efficacious in medicine. Granting that a certain degree of chemical knowledge is requisite, it does not follow that you should be scientific and accomplished chemists. It is not necessary that you should dive into all the arcana of the science, or have your memories loaded with atomic numbers, symbols, and equivalents.

Let me repeat with respect to chemistry what has been already observed concerning botany. Students should attend one or two courses of this science as preparatory to the study of medicine, and during the period of that study they may attend another, in order to keep up and improve their knowledge; but they should never allow chemistry to cause them to absent themselves from the hospital for a single day. Theoretical and philosophical call for your attention less than animal and pharmaceutical chemistry. But you are told that you may be called on to decide questions of medical jurisprudence, which demand an accurate knowledge of chemistry; that you will be required to test poisons, and detect them when accidentally or purposely mixed with food or drink. What should you do in such cases? Why, do not undertake any investigations of the kind, refuse to make them, refer them to those who are competent to the task. Where will you find a man engaged in the practice of physic fully capable of deciding such questions? What practising physician or surgeon is competent to enter at once upon an investigation of this nature? I have lectured some three or four years on medical jurisprudence, and have bestowed a good deal of attention on the subject, and yet if called on to decide a case of poisoning, I would refuse, and say I was incompetent to the task. What then is to be done under such circumstances? This is a matter of deep importance to society. It is of the utmost consequence that the wretch who poisons should not escape, and that the innocent should not suffer. It therefore behoves the Government to employ and pay persons capable of deciding such questions. Then, and not till then, will the task be duly performed, and the decisions be such as

the public can look up to with respect and confidence.

So far with respect to a knowledge of chemistry as connected with the choice and prescription of medicines, or the analysis of poisons. As to any benefits derived from analytic chemistry in solving the problems of vital action, or elucidating the functions of the various organs in health and disease, they may be said to be few, unimportant, and inconclusive. Few and scanty, indeed, are the rays of light which chemistry has flung on the vital mysteries. I am not aware that it has revealed any of the master secrets of the organism, or detected the sources of those important aberrations from normal action which we are called on to study every day and every hour. Chemistry has failed most remarkably in revealing the arcana of life; and, notwithstanding all her boasted discoveries, we are still very little in advance of those who practised the healing art some centuries ago. Chemists, the ablest of their class, have bestowed the most minute and unwearied attention on the analysis of fibrin, and gelatin, and albumen; and what have they discovered? Simply this: that substances so apparently distinct in their vital relations, and so different, or even opposed, in their physical properties, are analogous compounds; that there is scarcely any difference in their elementary composition; and that their atomic constitution is nearly identical. How long have chemists laboured in attempting to detect the cause of animal heat? How many experiments have been made for the purpose of ascertaining the effect produced on the air by respiration? How many able and ingenious men have sought a chemical explanation of the difference in point of colour between arterial and venous blood? All these investigations have proved indirectly useful, but none of them have revealed the secrets sought; and we are still in profound ignorance of the powers which direct and modify the unceasing operations of the laboratory over which *life* presides—that mysterious influence which, like the Deity from whom it emanates, is invisible, inscrutable, incomprehensible.

So much for the light which chemistry has shed on the vital actions, and on the nature of organized compounds. There are, to be sure, one or two instances in which a rough examination of some organic products is necessary; as, for example, of the urine in certain cases of gout, gravel, and dropsy. But even in these instances a few simple rules will suffice, and sufficient information may be obtained by one moderately acquainted with chemistry. Generally speaking, the chemical knowledge requisite for the study of

disease is very limited; and those who are engaged in the practice of medicine are well aware, that cases demanding an accurate or extensive knowledge of chemistry are of extremely rare occurrence.

Let me now advert to a serious inconvenience which the chemists have imposed upon the medical world. They have, it appears, not only assumed to themselves the privilege of naming our medicines, but also of changing those names every five or six years. One of my ablest and most diligent pupils (Mr. Moore) has taken the trouble of drawing up a table, shewing the various names which have been successively bestowed on each substance since the days of Lavoisier. I have the table here before me, and I find that most chemical substances have, in the space of fifty years, undergone at least five changes. Of course, as the march of chemistry progresses with accelerated speed, we may give our nomenclators credit for an increased tendency to revolutionize the chemical vocabulary, and conclude that they will change them five times within the next fifty years. In 1890, how will a man be able to recognise a substance whose name has undergone ten mutations? I am anxious to dwell on this defect, as being pregnant with perplexity and confusion. It would almost seem as if some enemy to our profession had invented the chemical nomenclature for the purpose of retarding the advance of practical medicine. Of what use will a *Præticæ of Physic*, published in 1800, be to the reader who peruses it in 1900? We all know how easily the mind of man is deterred by difficulties; how few there are who will submit to the labour of becoming genealogists in chemical names.

Many and able men foresaw this difficulty from the beginning, and raised their voices against the adoption of names meant to convey a knowledge of the chemical composition of mineral and saline medicines. Bostock and Murray have both written ably on this subject, and I regret much that their advice has not been duly weighed and considered. In practice, many serious inconveniences arise from this vacillating state of chemical nomenclature. Every apothecary knows that mistakes occur from day to day, owing to the shifting character of chemical nomenclature, and I think it is time for us to bestir ourselves, and make a stand against the useless and dangerous innovations of the chemists. We should come forward boldly, and declare that we will not be made the slaves of names. Compare our last *Pharmacopœia* with its immediate or penultimate predecessor, and the difficulties a physician has to encounter will be obvious. Are we to be per-

petually called on to learn new names? Must an artificial method of forgetting become even more necessary than a *memoria technica*? Must my prescriptions of 1818 be translated into a new language, if I wish to employ them now? It is time, then, to protest seriously against having our memories loaded with a polyglot vocabulary, and our ideas confused by a perpetual alteration of names. I do therefore assert boldly, that much benefit would accrue from reverting to the old system, and employing names which have no direct reference to the substances. I do not see any reason why we should not continue to call calomel, calomel; nor do I see any advantage in giving it any of the numerous modern appellations supposed to indicate its chemical constitution. I am glad to find that this view of the subject has the able support of Dr. Sigmond. He quotes Professor Brande as being of opinion that "it is very inconvenient to alter pharmaceutical terms according to the changes in chemical nomenclature; and as physicians in practice have not come to accord in this particular, I can see no objection to the term *calomel* for one substance, and *corrosive sublimate* for the other, pharmaceutically speaking." It is a subject of deep regret, adds Dr. Sigmond, that the attempt should be made, because it never can be successful; for some chemists will call calomel *protochloride*, others *chloride*, and some denominate sublimate *perchloride*, others *dentochloride*, and others again, as does the Royal College of Physicians, *bichloride*.

What is the use of a name? To designate a thing—to point out any substance, so that when we call for it we may get it, and nothing else. This is all that is necessary. When you tax a name beyond this, you exceed the limits of ordinary language, and demand too much. The old names for our medicines are not inferior, in this respect, to the modern ones imposed on us by chemists. Tartar emetic is a good and significant name, and yet I perceive it has been altered several times before, and again in the last edition of the *London Pharmacopœia*. Why is it that the preparation of bismuth used in pyrosis has been three times changed in my own memory? What alterations have not the carbonates of iron and of alkalies undergone? As for Fowler's solution, corrosive sublimate, Mindererus's spirit, and Æthiop's mineral (all good standard names), they are now nearly extinct, and have been superseded by a new generation likely to prove as unstable as their predecessors. Many other substances have undergone the same fate. Where will the revolution stop? Indeed we seem, at the present moment, as far removed as ever

from the establishment of a stable system of chemical names. The progress of investigation discloses almost daily new views of the mutual relations between the elements constituting compound bodies; the atoms associated together are divided and subdivided into new groups, and, consequently, the symbolical representation of every compound assumes a new configuration, and is subdivided by brackets, altering their places with each successive advance of science. The labours of Bornsdorff and Hare already threaten the nomenclature of Berzelius, and the *chlorure platinosopotassique* of the latter, now considered as a compound of chloroplatinous acid and the chlorobase of potassium, must then be called chloroplatinite of potassium.

If chemical names are still to be formed with the view of expressing chemical composition, there is no end to the complication and length at which they must arrive. If they express composition, it is worse than useless, were they to do so incompletely. A name whose structure designates the nature of the thing named must, in chemistry, to be serviceable, designate it with perfect accuracy. Professor Kane has analyzed, in one of his very able papers, a crystalline substance obtained by boiling the white ammonia subnitrate of mercury with solution of ammonia. Suppose this substance to be introduced into the Pharmacopœia, how can it be named in conformity with the principle which attempts to make each name expressive of the composition of the matter named? its composition is stated by Professor Kane to be—one atom of nitrate of the oxide of mercury, *plus* two atoms of oxide of mercury, *plus* one atom amide of mercury, *plus* two atoms of the nitrate of the oxide of ammonium, *plus* two atoms of the oxide of hydrogen. Even if the ingenuity of chemists had surmounted the difficulty of inventing a name capable of expressing the nature, number, and mode of aggregation of the above elementary atoms, is it probable that a name, so gifted, would be of a length manageable by either the tongue or the memory? Is it certain that future experiments may not unfold new views concerning the arrangement of the constituent atoms, and thus nullify the old, by requiring the adoption of a new designation?

I would not be understood here as wishing to depreciate any department of human knowledge. Far be it from me. Besides, the attempt would be useless. But I am anxious that you should concentrate all your energies on the proper objects of medical pursuit, and devote the largest share of your attention to those acquirements which will render you good practitioners. I have seen students led astray by false

notions, wasting half of the time which should be spent in hospital, and by the sick bed, in wandering through the fields on botanical excursions, or working in the laboratory, engaged in the solution of some unimportant problem. Now this is not what will teach them to relieve suffering and cure disease. When I look round me, and behold so many young gentlemen entering upon an honourable and important profession, I feel that my responsibility is great. I consider you all as instruments of good or evil, and cannot help being conscious that I should be guilty of a great crime, did I not use every means in my power to render you able and efficient practitioners. The teacher of clinical medicine, gentlemen, occupies in every nation a post of heavy responsibility. But when he happens to preside over the medical education of those who resort to the wards of a metropolitan hospital, when the metropolis is a British one, and the hospital destined to send forth annually practitioners to every quarter of the globe—to North and South America, to New Holland, to the Cape of Good Hope, to the East and West Indies, and the countless isles which, in either hemisphere, are visited by the British flag, then indeed does that teacher become himself an instrument of good or evil, to an extent which it is fearful to contemplate.

He who gives instruction to a clinical class in Berlin, Stockholm, Vienna, or Paris, has much to answer for, if he discharge not his duties with zeal and diligence. Yet if he fails to make his pupils good practitioners, their errors, however deplorable, are circumscribed within comparatively narrow bounds, and limited in a great degree to their own countrymen. But the British teacher sits in the centre of a circle far wider than Sweden or Prussia, or Austria or France; his pupils are to be met with practising in every climate, exercising their art in almost every habitable region of the globe, and dispensing the blessings of health to all races of mankind;—to the hardy white settlers of Canada, the aboriginal red skins of North America, the negroes of Jamaica, the hottentots and Caffres of Africa, and the countless tribes of Hindostan.

In truth, gentlemen, the British teacher of practical medicine exercises an influence without parallel in importance and extent, and his opportunities of benefiting or injuring his fellow men are incalculably great. If he neglects his duty, if he teaches erroneously, his negligence and his errors in practice are multiplied indefinitely, by means of those whom he ought to have better instructed; the scene of his guilt—for it deserves no better name—becomes fearfully enlarged, for there is no

country so remote that it may not contribute victims to the incapacity of his pupils. But if, on the contrary, he works with zeal and diligence; if he labours conscientiously and perseveringly in performing the important task he has undertaken, a compensation awaits him, to which scarcely any member of any profession can attain. Can any reward exceed in value the reflection that he has assisted, materially assisted, in imparting practical knowledge to multitudes of enterprising young men, who, year after year, leave our hospitals to engage in the sacred duties of the medical profession, throughout the world? Is it not a high privilege to be enabled to combat death, and conquer disease, as it were by proxy in so many different localities? Can man enjoy a purer, prouder, more gratifying reflection? When I hear that a favourite pupil, who has acquired a solid stock of practical knowledge in this hospital, has settled in any particular town or district, I cannot help feeling, on the part of my colleagues and myself, that we have been the humble means of conferring a blessing on the people entrusted to his care; and I cannot refrain from congratulating myself upon holding a situation which multiplies a thousand fold our efforts to be useful, and enables us to stretch forth our hands to heal men of all nations and languages. The hero and the despot may extend a sovereignty over distant regions—may exert an unlimited control over millions of vassals—may dispense honours and rewards, or inflict punishment and death;—they may, like Alexander, grieve at the narrow limits of a conquered world, and sigh for other scenes of glory;—but they cannot chase away pain; they cannot bid the burning thirst to cease, or give back repose to the sleepless; they cannot impart feeling or motion to the paralysed, or sight to the blind; and above all, they cannot imitate that almost godlike function of the healing art, by which man is enabled to recall to his fellow-man reason long banished, and restore to society the hapless victim of insanity.

Gentlemen, the profession we have embraced is the noblest that can engage the mind of man, when diligently cultivated and conscientiously practised; but it requires great and persevering industry to enable the student to master all the difficulties that beset his path. Feeling this strongly, I have trespassed perhaps too long on your attention; but I thought it my duty to lay before you, as fully as I could, those views which I deemed best calculated for your adoption in the acquirement of practical knowledge.

NATURE AND TREATMENT OF DELIRIUM.

To the Editor of the Medical Gazette.

SIR,

SHOULD you consider the following observations worthy of publication in your GAZETTE, they are very much at your disposal.

Your obedient servant,

M. B. GALLWAY,
Assistant-Surgeon Royal Artillery,
Woolwich.

September 20, 1838.

The subject of delirium is generally looked upon by the practical physician as one of the most obscure in the chain of morbid phenomena he has to deal with; whilst the frequency of its occurrence under various diseased conditions of the system renders the affection not a little familiar to his eye.

My object in approaching so acknowledged a *terra incognita* is not, I regret to say, that I have any fresh contribution towards its elucidation to bring into the field, but rather to awaken a more lively inquiry amongst the profession as to its real nature and causes.

My attention has been much directed of late to the question before us, from the very varied and opposite conditions of the system under which I have noticed its presence, as well as from the embarrassing feature it has proved in a large number of fevers of the adynamic type.

That well established law in the economy of nature, which inseparably connects a change of function with diseased action in an organ, sufficiently explains the occurrence of delirium, when the cerebrum or its meninges may be the seat of inflammation, because the discharge of the intellectual faculties being the primary and most important function of the brain, nature would not be acting up to her own ordinances, were not the peculiar office of this organ to be interrupted, when invaded by disease. Having lost the power of performing its natural function, the brain becomes "incapable of any exertion, and is carried along with whatever idea presents itself." I need not, therefore, bring under further review the delirium of phrenitis, but proceed at once to the objects I have had mainly before me, viz., that of noticing the delirium which

occurs under different states of the system, where, though strongly manifested during life, the brain is found organically healthy after death.

Let me, *imprimis*, bring forward the remarkable delirium that sets in early in the course of some fevers, characterized, from their commencement, by low or adynamic symptoms.

Delirium, in such cases, is often one of the earliest attendant symptoms. This may or may not be ushered in by apparent signs of fulness in the head.

The cautious practitioner will perhaps be here induced to bleed, either generally or locally; still "feeling his way" with his patient's pulse in his hand. He does so, perhaps, from an acknowledged doubt in his own mind as to the state of the brain at the moment; lulling himself the while into the conviction that such a measure at least will be harmless—perhaps a safety-valve against excessive cerebral action.

But what will the "routine doctor" do in such a case? What are *his* views as to the causes and nature of the delirium? Alas! I am afraid it is no exaggerated picture when I affirm, he will too often view this condition as one of inflammation, or, at least, of extreme congestion; and, determined to "knock down the pulse at a blow," abstract a large quantity of blood from the arm; to say nothing of the application of various instruments of professional torture to the head, in the shape of blisters, cupping-glasses, &c.

The practitioner who applies such a remedy to the disease before him, and fails to husband his patient's strength for the long and protracted struggle that may await him, too soon discovers the fatal error he has been enticed into by his own ignorance, and uselessly now exclaims, "Would I had not bled the man!"—discovers, I say, that he has indeed dealt his patient a knock-down blow, from which the chances are that he is effectually disabled from rising again.

A few days, or even a few hours, may witness this patient lapsing into a state of fatal prostration; attendant upon which change will be an increase in the delirium—not in its degree, but permanency—if it has not already passed into confirmed coma.

The only confirmation of his views of a diseased brain which the practitioner I have here spoken of may find in this

case, on a post-mortem inspection, will probably be in a blanched state of the organ throughout, or (what may be resolved into much the same condition) isolated spots of congestion, the result of the loss of tone in the venous system of the head; and the latter the result probably of his own treatment—

"*Exsuperat magis—ægrescitque medendo.*"

On what, then, does this condition of the brain depend, if neither on inflammation nor congestion?

This is the question I would urge most anxiously on the profession; because on its solution rests so entirely the fate of a large number of fever patients at the present day. I cannot satisfy my own mind with any explanation sufficiently rational or plausible, whereby I could directly point out the condition which gives rise to it: I will not say the condition of the head itself, because I am satisfied of this much, that there is no primary action within itself giving rise to it, believing its function to be interrupted by other and more distant or general causes.

The imperfect transmission of the blood through the lungs, and its consequently mal-oxygenated and deleterious quality (the result either of prostration of the heart's action, or determination to the pulmonic system), may perhaps so stifle and oppress the brain, as to render that organ incapable any longer of exercising its natural office, and a state of low delirium may be the consequence. Nay, congestion, I will allow, may even, from such a cause, take place within the head. Congestion! that fashionable and convenient veil to conceal our real ignorance of some of the morbid states of the cerebrum. But is the lancet the remedy to relieve it? Because a mechanical obstacle in the lungs opposes the free circulation of blood in the head—because it stagnates there, will abstraction of its momentum enable it more readily to pass on? It is not from an excess of blood that stagnation takes place, but from a barrier to its progress in a distant quarter. Supposing, as I suggested before, the delirium to depend on the destructive quality of the blood on the brain itself, would a reasonable man expect to improve that vicious quality by rendering the amount of its momentum less? Assuredly not. As well might a landowner hope to destroy a

malaria on his property, by *partially* draining the stagnant marshes that gave rise to it: his efforts would not be less ineffectual, so long as the quality of what remained was unaltered, and the current unrestored.

It is not improbable, I think, that this peculiar form of delirium may depend, in some measure, on the defective circulation of the blood in the brain depriving that organ of the degree of stimulation necessary for the discharge of its function; just as we see vertigo and a failing in the powers of the brain produced in persons who have deteriorated the quality of their blood by those excesses, which, at the same time, exhaust their nervous power,—a state of the cerebrum which Mr. Travers describes as “probably arising from an imperfect injection of the medullary substance.”

I am much disposed to attribute the form of delirium now under review conjointly to the loss of tone in the vessels of the brain itself (whereby the organ is deprived of its natural stimulus), and to the difficulty of the blood's transit through the pulmonic system, together with its non-purification in that quarter. It may be contended, however, that in relation to the pulmonic circulation, I am alluding more to the remote than proximate cause of the phenomenon in question. Be it so; I am not anxious to hold out on so nice a point of disquisition; but I am altogether at issue with those who contend for a primary and positive action in the brain itself being the *rationale* of the matter. Here lies the key-stone of the fabric I would build up on secure ground; and hereon, also, I deem the importance of the question to hinge.

It is really trifling with the serious subject before us, to make even an allusion to the question of inflammation here. But knowing that there are individuals who inseparably associate the symptom we are speaking of with inflammatory action, I beg to impress the importance of the subject with increased emphasis upon them, and trust they may yet learn to reflect on the chain of evidence that stands forth against their false doctrines.

Bateman, indeed, I am aware, remarks, that subacute cerebral inflammation sometimes supervenes under circumstances of great general debility; when the nature of the one affection absolutely contra-indicates the treatment

which the nature of the other as decidedly requires. But such a statement does not impinge upon the peculiar kind of cerebral affection I have spoken of, or invalidate the deduction I before made.

Dr. Philip Wilson, in his excellent essay on the Nature of Fever, has on the present question these pertinent remarks:—“Delirium much less frequently arises from excess of excitement than from debility; and in the first paroxysm of fever the excitement is seldom such as to produce it.

“The symptoms of excitement are few and simple; those of debility numerous and complicated; one cause of which is, that excessive excitement never continues long; debility, on the contrary, is of long continuance; during its influence there is time for various changes to take place.”

Let me adduce in this place the remarkable words of an author who has dealt copiously and most ably with the subject-matter of our present question; I allude to Van Rotterdam's prize essay on Blood-letting in Fevers, read before the Academical Society of Paris in 1811:—

“It is delirium from debility of the cerebral organs that is most frequently observed at the commencement of, and in the course of nervous, putrid-nervous, ataxic, and other fevers of that kind; it is almost always of a pacific character, and is known by other symptoms of atony, such as lassitude, slight headache, vertigo, loss of memory, indifference, trembling of the limbs, weakness of the pulse, paleness of the countenance, limpid urine, &c. If in this case there is otherwise no symptom of irritation, all blood-letting is absolutely hurtful.”

Tissot thought the delirium of fever so generally sympathetic, that he says, “Of twenty cases of delirium, eighteen have their source in the abdominal viscera.”

And Galen teaches that the delirium which supervenes in the height of fevers is not always owing to the direct affection of the brain, but most frequently to its sympathetic connexion with the *primæ viæ*,—an opinion which we again find in the doctrine of Boerhaave (*De Morb. Nerv.* p. 360, *et seq.*)

Dr. Armstrong, in his Treatise on Fever, says, “Delirium is one of the most ordinary symptoms of typhus

under all its modifications; but, singly considered, it is by no means conclusive as to the real state of the brain or its appendages." In another place we find him stating on the same subject, "Delirium is a common attendant on typhus at all times, but particularly when any part of the thorax is attacked with inflammation, which, impeding the transmission of the blood through the lungs, tends to prevent its free return by the veins from the brain. But it is not improbable that the delirium may also, in part, depend on those inexplicable sympathies which exist in the nervous system. Certain it is, that I have met with some cases accompanied by great intellectual derangement from the beginning, in which the minutest dissection after death could detect no vestige of cerebral disease, though in all an effusion of serous fluid was found in the pericardium, with some appearance of inflammation on its surface, and on that part of the pleura which covers the diaphragm."

On this last pseudo-morbid appearance I may quote the words of Dr. Marshall Hall, from his treatise on the Morbid Effects of Loss of Blood:—

"There is, in extreme cases of exhaustion, a general tendency to serous effusion, both into the internal cavities and into the cellular membrane. This effect of the loss of blood has been very long remarked by medical writers."

"Dissection shews that the drowsiness which we sometimes meet with in putrid or nervous fevers is not always owing to compression of the brain, but that it proceeds frequently from its debility, or that it is only sympathetic; and if we consider attentively that it is not uncommon to find the brain without any alteration after soporose affections (although, however, the contrary often happens); that very frequently even anatomists of the first order have not been able to discover by dissection the cause of fatal apoplexy in the brain; that, besides, we often observe, independent of fevers, soporose diseases caused by poisons, or excesses in venery, in wine, &c.—affections which are cured by emetics or purgatives; if, I say, we consider all these facts, we shall be readily convinced that, in fevers, soporose affections may arise either from simple debility of the cerebral organ, or from its sympathy with the primæ viæ; and we shall no longer be surprised at

seeing them treated by tonics and evacnants." Such are the words, again, of Van Rotterdam, in confirmation of the position I have assumed.

Cullen considered the delirium as arising either from simply atony of the brain, or from a less degree of debility, accompanied with determination to that viscus; and Dr. Burne, in his treatise on the Adynamic Fever, considers the whole affection of the head in that disease of trifling moment—a mere will-o'-the-wisp—a sympathetic affection.

[To be continued.]

CASE OF ENCYSTED TUMOR,

CONTAINING SEROUS FLUID, OCCURRING IN
THE BRAIN,

Mistaken for Abdominal Disease.

(Communicated by Sir James M^cGrigor, Bart.)

PRIVATE Henry M^cLoughlin, 59th regiment, æt. 34, admitted 10th June, 1838, labouring under hepatitis chronica; a Scotch labourer of sanguine temperament and thick-set frame, complaining of pain over region of liver, aggravated on pressure; headache; pulse 90, strong; tongue covered with a white fur; and bowels regular. Considers the symptoms a renewal of an old complaint, contracted three years ago at Gibraltar.

Mittatur sanguis ad ʒxxx. R Pil. Cal.
c. Colocynth, ij. nocte. Diet, spoon.

June 11th. — Dyspnœa, with tightness across the chest; right side looks large.

Hab. Sulph. Magnes. ʒj. statim.

12th. — Pain continues.

Applicat. Emplast. Canthar. lateri dextro. Sumat. Mistura Salin. Antim.
ʒj. quartis horis.

13th. — Complains of pain in the head; skin sallow.

R Pil. Hydrarg. gr. v. bis indicies. Cont.
Mist. Salin.

14th. — Tongue clean, headache less, and bowels regular.

Omit Pil. Hydr. Diet, half.

17th. — Convalescent.

18th. — Discharged.

July 4th. — Re-admitted, complaining of sickness and vomiting; headache, and "blindness," when the headache comes on, which continues some minutes.

R Pulv. Ipecac. gr. xv. Antim. Tart,

gr. ii. Aquæ, ℥ii. M. Statim sumend. Diet, spoon.

5th.—Headache continues, and affects him *round* the head; appetite bad, and tongue foul.

R Pulv. Rhei, ℥iss. Sulph. Magnes. ℥iss. Aqua, ℥viii. M. 3j. bis indies.

7th.—Better.

9th.—Rapidly convalescent.

11th.—Discharged.

July 18th. — Re-admitted, with a throbbing pain in the temples, and other symptoms of his old complaint. [On this occasion the trial of putting a small blister on each temple was made.] Diet, spoon.

22nd.—Diet, low.

23rd.—This man's behaviour in hospital is unaccountably obstinate and singular. Exclusive of the languor and a certain sleepiness attendant on his complaint, which is a complication of chronic hepatitis and dyspepsia, his manner is of the most morose and sullen character; scarcely answers a question.

Continuator Mistura.

24th.—His health appears good; eats his meals, goes about, and complains of no pain. Diet, half. Discharged.

30th.—Re-admitted, after having been sick at stomach last night. Makes no further complaint than that his head aches a little. Tongue covered with a thick white fur; pulse 75; bowels costive. Has a trembling, with apparent lameness of right side.

Sum. Pulv. Purg. statim.

6 P.M.—Is taken with some shiverings and insensibility; pulse 110, full; face flushed; pupils dilated; and breathing stertorons.

Mittatur sanguis ad 3x. ab arteriâ temporali.

R Ol. Tigllii (Croton) mis. statim; et habeat enema.

After bleeding, he breathed more easily, and raised his hands towards his head; but soon he began to get worse; teeth became clenched, and breathing convulsive; and at 10 P.M. he expired, the medicines not having operated.

This case is thus given in detail from the case-book, in order to present it in as connected a form as possible, and permit the observation of those symptoms which throughout indicated cerebral disease, but which during treatment were mistaken for symptoms of

disease of the abdominal viscera, and subsequently became the objects of so much mystery. The naturally sullen and obstinate disposition of the man, increased when suspected of scheming, for which he had a notorious celebrity in the regiment, rendered also the elucidation of his case more difficult. It will be seen, from the morbid appearances, that the nausea and vomiting were evidently sympathetic affections of disease in the brain; the occasional disease of vision and the moroseness and stupidity that characterized his habits were conspicuous symptoms of cerebral disease also. The symptoms with which he was admitted on the 30th July indicate an attack of partial hemiplegia, and that occurring on the side opposite to the seat of disease in the brain.

Post-mortem examination.—External appearances. Body muscular and fat; testicles ecchymosed, and limbs rigid. Head.—Veins and meninges turgid with blood. Several small round masses, which were attached to the brain, and of the like substance, protruded through the arachnoid membrane. At the anterior part of the left hemisphere of the brain was a cyst containing at least six ounces of limpid serum, with a layer of thin jelly covering its walls, which were thinnest at its anterior part, but had no opening. The lateral ventricles contained very little fluid, neither was the plexus choroides particularly vascular, nor was there any other morbid appearance. Thorax.—Heart covered with a considerable quantity of fat, and the right auricle greatly enlarged and thinned in its walls; valves not altered. Lungs œdematous, and considerably gorged with blood; adhesions at the summit of right lung. Abdomen.—Liver enlarged, and weighing 3½ lbs. and fatty, staining paper very thickly with oil when heated; two large cicatrices of former abscesses on its surface. No unusual appearance in the gall-bladder. The rest of the viscera were healthy, but distended with fæces and air.

The cyst was a transparent jelly-like membrane, pretty firm, and about as thick as the cornea, easily detached. On immersion in spirits it became contracted and more opaque.

CICERO.

THE MANAGEMENT OF MAD-
HOUSES.

A USEFUL, though somewhat angry, treatise on this subject has lately been published by a physician in the North of England*; and though we venture to hope that matters are not managed quite so ill as he represents them to be, even in the most celebrated asylums, still, those who recollect what accumulated horrors were formerly produced by neglect and the want of supervision in many mad-houses, will not be sorry to see an active critic come into the field, though he sometimes seems to dip his pen in gall rather than in ink.

Dr. Crowther says, in his introduction, that he is aware that by submitting his pamphlet to some hacknied writer, he "might very materially have improved the style and euphony." He fears, however, that by this method he might have lost in sense what he would have gained in sound. Now, it is our opinion that if he had hired his hack from some first-rate literary stable, he might have got much more than this out of him, and that a well-taught mercenary would have improved the sense as well as the prosody. For instance, at the beginning of the next chapter, where the author discusses the supposed advantages of the division of labour in medicine, he says that "the prejudice on this subject is so strong, and the explanation so complicated, that I despair

of conveying conviction to the unlettered mind." But why "unlettered mind?" Two lines before, Dr. Crowther wants to make the subject intelligible to well-educated men; and in the previous chapter he says he has printed his observations in order to communicate them "to several influential individuals, who possess the power and the will to improve our public institutions." Surely neither the influential individuals nor the well-educated men have unlettered minds. We agree with him entirely, and we suppose that every one does, when he asserts that the mad-doctor ought to have had a complete medical education. But after this education is finished, and the physician has devoted himself to the treatment of the insane, we fear that it will not always be in his power, however much it may be his wish, to keep up any considerable quantity of general practice. This, however, will chiefly depend on the size of the town where he lives. In London, where practice has so great a tendency to subdivide itself, he will commonly find that the great mass of ordinary patients will select the ordinary physician, and that he must be content, as he well may be, with the golden rewards appropriated to his particular branch of the profession. He will have no reason to be discontented with the appropriation clause. In small towns, we apprehend, this strict division can rarely, if ever, occur; and we therefore rather think that Dr. Crowther is censuring the erroneous theory concerning the subdivision of medical labour which he conceives to prevail in the breast of certain laymen, than any great practical evil existing in the profession.

An interesting point discussed by Dr. Crowther is, whether the spread of dysentery in our lunatic asylums is a necessary evil, or the result of negligence, where, of course, he inclines to the latter alternative. In the Hanwell Asylum

* Observations on the Management of Mad-Houses, illustrated by Occurrences in the West Riding and Middlesex Asylums. By Caleb Crowther, M.D. formerly senior physician to the West Riding Pauper Lunatic Asylum. London, 1838.

he says that seventy-five patients died of diarrhœa and dysentery in five years; while in the pauper Lunatic Asylum of the West Riding of Yorkshire, thirteen patients died of dysentery, besides three other persons*. Dr. Crowther thinks, with some probability, that the disease spreads by infection, owing to the bad state of the water-closets, and the neglect of due superintendence. In the printed rules of the Hanwell Asylum, it is stated "that the keepers are expected also to examine the stools and urine of the patients, so as to be able to report their state, and every particular concerning them." Dr. Crowther, however, is quite sure that this rule has not been acted upon, otherwise so many cases of dysentery would not have occurred, as the director would have ordered any patient attacked with the disease to be separated from the rest, and thus stopped the infection betimes. We do not know whether our readers will be convinced by this syllogism, but perhaps they will place more confidence in what he says about his Yorkshire asylum, for *Pluris est testis oculus unus, quam auriti decem; i. e.* one fault seen at Wakefield is of more importance than ten discovered at Hanwell by the help of books and reports. He says then, that "so little attention is paid to prevent the spread of this disease at Wakefield, that even a patient in a double-bedded room, when seized with it, is not sent to the infirmary, nor is his companion in the adjacent bed sent away. The infirmary is certainly perched in the most inconvenient situation possible, at the summit of the building. Since this remark was written, I hear that one dysenteric patient has been sent into the infirmary."

But though he fears, and probably with reason, the spread of dysentery by infection, he has no sympathy with those who dread the contagion of Asiatic cholera. When the disease prevailed in that neighbourhood, the Visiting Justices issued an order that no one should be received from districts where that disease existed. But "this order manifested the great ignorance of Justices." We suspect that it is not a very easy thing to please Caleb Crowther. Nevertheless, his evidence is valuable, and, if substantiated in all points, it is of the last importance. Thus he asserts that in large asylums the office of removing the stools and urine is performed by the insane patients, who are incapable of giving a correct account of them to the medical attendant; and he mentions a case which occurred when he was Physician to the West Riding Asylum, where a patient was presented to him for the first time a day or two before his death, "who, from the intestinal disorganization apparent on the autopsy, must have been affected with the disease for some weeks."

In the chapter on inquests held at asylums, there are some severe observations; but, taking the facts for granted, there can be no doubt of their justice. In 1833, a gentleman of fortune, having a strong suicidal tendency, was admitted into the West Riding establishment. Two or three days afterwards he destroyed himself with a razor that he found in the ward in which he was confined; or, as it is afterwards stated, which he found in the lodging-room of an assistant-keeper. The carelessness through which this gentleman was allowed to possess himself of a razor, the absence of the director from the asylum, and the impropriety of admitting a man of fortune into an establishment intended only for the poor, are all commented upon by the author with suffi-

* It is not stated in this chapter over how many years these sixteen deaths were spread; a "hacknied writer" of ordinary *vous* would have nudged the author here, and asked for dates. From a table in the 25th chapter it appears that the period was five years.

cient rigour. The last item of accusation, however, seems capable of being interpreted into a decided compliment to the asylum. Is it not possible that the relations may have sent the patient rather with a view to expedite the cure than from the sordid motive of economy? It seems that formerly an inquest was held at this asylum on the death of every patient; this practice has been given up, Dr. Crowther approving. When we consider, however, how very frequently it must happen, when an insane person dies, that his friends suspect his death to have been caused by violence, inflicted either by himself or by a fellow-sufferer, we must confess that we are not quite sure of the policy of the change. In other words, the law supposes inquests to be held in every case of suspicious death: and is not every death of a lunatic suspicious?

“Ought public lunatic asylums to be placed under the care of one medical man?” Dr. Crowther answers no; and is probably in the right, though the subject is environed with difficulties. Of these, however, he notices, as is usual with him, only one half, namely, those that belong to the scheme which he opposes; but those that belong to his own plan are worth noticing too. If an establishment is under the care of one man only, he can do, and say, and publish, what he pleases; and if the visitors are mere laymen, it will be extremely difficult to detect even material mismanagement. If, again, we suppose the resident medical officer, like the apothecary of an ordinary hospital, to act entirely under the guidance of a visiting physician, the patients will lose the advantage they might derive from the control of a superior kind of superintendent, who, in common phrase, would be unwilling to play second fiddle to another man. Dr. Crowther’s plan to make all this smooth is not a very commendable one; he gravely

proposes, that “all the superior officers ought, on their appointment, to engage to communicate to the governors every impropriety of conduct which falls under their observation; and for this purpose the physicians, surgeons, apothecary, clerk, director, and matron, being all separate and independent appointments, ought to be examined by the governors, separately, several times a year.”

Now, really, if we read this statute aright, it seems to establish an asylum staff, consisting of mere informers—Byers multiplied by 8. To make the system perfect, each of these lynx-eyed officers should be furnished quarterly with a small black book, to be filled, as best it might, with a list of his neighbours’ peccadilloes—with rewards proportioned to the gravity of the offences discovered. No! no! other systems may be indifferently bad, but this would be intolerable.

Another question is, how ought the medical directors of asylums to be elected; which, of course, might be included in the more general problem of, how ought medical officers to any public institution to be elected? Manage it how you will, objections not trivial, nor merely plausible, but sound and solid, may be made to every method. Whether a physician be elected by county magistrates, or a large body of subscribers, or a select council of three or four, or by a *concours*, or on the faith of testimonials, or by any other method that ingenuity may devise, there will always be abundance of room for partiality or mistake. A man may be elected because his father was before him, or because he is a distant relation of Lord Hammer-smith, or because he is a skilful electioneerer, or a Muggletonian, or a good diner-out, or for a hundred other reasons independent of his medical merit. Dr. Crowther, however, has a scheme to avoid all causes of error, and get the

best man elected. Let medical officers be appointed, he says, by a Minister of Health, assisted by a medical board. We do not positively say that this plan is indefensible, but the objections are obvious enough. One is, that it tends to an injurious centralization; the men of the West Riding, or any other, would be unable to elect a doctor to their own asylum, and must await the fiat of a London board. This referring every thing to the metropolis, as if the country population of England were unable to transact the common business of life, has been a very unpopular part of the New Poor-law, and most deservedly so. Another objection is, that the board, if inaccessible to canvassing, must necessarily be guided in their choice by the dry answers of the candidates to the examination questions; whereas, in the popular election, their personal or moral fitness will have some influence on the body of voters. With elections by magistrates, Dr. Crowther is, of course, most deeply dissatisfied. The magistrates, supposing them to be without partiality or prejudice, can only judge, he says, by certificates, "and we know very well that the most impudent and boasting men, however ignorant they may be, will often produce the greatest number of good certificates."

When Dr. and Mrs. Ellis resigned their situations at Wakefield, the magistrates advertised for their successors in the office of Director and Matron (without stating that they meant to select man and wife), and about seventy candidates came from all parts of the British isles. The magistrates now grew pale at the thoughts of examining a mountain of testimonials, and were at a loss how to proceed. In order, therefore, to cut the matter short, the justices, says the splenetic Crowther, "came to the worst possible decision,

which was, to elect a married pair to fill the vacant offices."

We trust that Dr. Crowther will forgive us if we confess that we should have been inclined to "come to the worst possible decision," likewise, by electing a married couple; but on the other hand we own that the probability of such a decision ought to have been intimated in the advertisement.

We will continue this subject on an early occasion.

RESUSCITATION OF MESMERISM.

WE thought that mesmerism had received its death-blow, and was defunct; but we understand that since Dr. Elliotson's return to town the Mesdames O'Key have made their appearance at University College Hospital, and that the learned Professor declares his faith in the *science* to be quite unimpaired. Now, with Dr. Elliotson's opinions as a private individual we have nothing to do; but if it be intended (as our informant surmises) to resume the exhibitions of these accomplished performers either at the College or at the Hospital, we think the other medical men owe it to themselves and to their school to take immediate steps for putting an end to all such mummeries.

WESTMINSTER HOSPITAL.

CLINICAL LECTURE

ON

FRACTURES OF THE FEMUR,

By MR. GUTHRIE;

With Remarks by the Reporter.

Caries of Os Femoris—Gun-shot Injuries of the Thigh—Various kinds of Fracture Bed.

JOHN AYRTON, æt. 26, a sailor, discharged wounded from the steam-boat employed by the Spanish Christino government to blockade that portion of the Basque Coast in possession of the Carlists, was admitted under the care of Mr. Guthrie, early in the spring. He was struck by a musket-ball on the right thigh, a few inches below the trochanter major. The

ball penetrated the muscles, glanced against the bone, and found its way out on the inner and upper side of the thigh, without injuring any of the great vessels. He was conveyed to San Telmo, and there skilfully treated by Mr. Rutherford Alcock. The gun-shot wound healed, and the man returned to his duty, but he remained lame. He was employed for several months afterwards on board the steam-boat, and ultimately worked his passage home to England. When admitted into this institution, he stated that he had had three or four gatherings of pus form and break in the neighbourhood of the gun-shot wound, and an examination of the limb shewed the existence of several fistulous openings, of which the nipple-like orifices well indicated the existence of caries in the subjacent bone. This was evidently a case in which the ball having injured the periosteum, death of a part of the adjacent bone had taken place, and more or less extensive caries produced. Influenced by this view of the matter, Mr. Guthrie made a crucial incision through the integuments and muscles, down to the bone. A trephine was then used, and several portions of carious bone removed. With the aid of a small circular saw, Mr. Guthrie detached all the unsound bone from the healthy. The wound was filled with lint, and the patient put to bed. A healthy suppuration was set up in the exposed surfaces; all the morbid osseous particles were detached. The wound healed in due time, and the patient was finally discharged with a serviceable limb.

Upon this case Mr. Guthrie delivered a clinical lecture, of which the following paragraphs contain the substance:—

“In the accidents of civil life, the bone is in general merely broken across, or obliquely, with the point thrust through the soft parts. In gun-shot wounds it is generally the reverse, the bone being much shattered, and not appearing through the integuments. If a musket-ball, in passing through the thigh, merely touch the bone, it may, as in this case, destroy a portion of the periosteum, of which caries is the usual consequence; or it may fracture it directly across; but it will generally do it obliquely, so as to cause some little shortening of the limb when cured, even under the most attentive treatment. But when a ball strikes the shaft of the femur, it shatters the bone in every direction, although it may not pass through. It does not merely break off four or five small pieces, which may be taken away by cutting down upon the bone, but it breaks it into large pieces, generally oblique, and very pointed, and which retain their attachment to the muscles inserted into them.

“The danger and difficulty of cure attendant on fractures of the femur from gun-shot wounds depend much upon the part of the bone injured. It is consequently useful to distinguish the bone into *five* parts. Of these, the head and neck included in the capsular ligament may be considered the first. The body of the bone which may be divided into three parts, and the spongy portion of the lower end of the bone exterior to the capsular ligaments, forming the fifth part. The fractures of the first of these divisions are, I believe, always ultimately fatal. The upper third of the body of the bone, if badly fractured, generally causes death at the end of six or eight weeks. Of those whose femurs have been badly fractured in the middle part I have seen but few escape, and then not with a useful limb. Fractures of the lower third of the body of the bone are least dangerous. Fractures of the fifth division are in a great degree dangerous, as they generally affect the knee-joint. Under all circumstances, a fractured thigh by gun-shot, even without particular injury of the soft parts, is one of the most dangerous kinds of wounds that can occur. Upon a review of the many cases I have seen, I do not believe that more than one-sixth recovered so as to have useful limbs; two-thirds of the whole died, either with or without amputation; and the limbs of the remaining sixth were not only nearly useless, but a cause of much uneasiness to the patients for the remainder of their lives, unfitting them for any employment, civil or military.”

Here the lecturer read a long extract from his own work on Gun-shot Wounds, recommending a more frequent and early recurrence to amputation in gun-shot injuries of the thigh than is usually adopted. He then continued:—“It is a difficult thing to persuade a surgeon, unaccustomed to the treatment of gun-shot wounds, or the patient himself, when he sees but a small wound, that amputation is necessary; and as cases of success have been heard of by all, whilst the fatal ones are buried in oblivion, many officers will not submit to it; they will rather hazard their future health and happiness, and undergo great sufferings for months, to save a limb, which, when cured, they find a useless burthen for the rest of their lives.

“Wounds from musket-balls, injuring the lower part of the bone, without communicating with the joint, do not require primary amputation; they are proper cases for delay, unless there be great destruction of parts.

“In order to secure a reasonable hope of success in the management of a com-

pound or gun-shot fracture of the thigh, it is desirable the patient should be placed on a proper bedstead, of sufficient height from the ground, to render him easy of access, and capable of affording him every necessary comfort and accommodation without moving. This will be best accomplished by a bedstead and mattress invented by the late Mr. Gardiner and myself in 1815. The one he died upon in 1817 is now at Mr. Knox's, 107, Jermyn Street. This bed is so absolutely necessary in cases of diseased hip and spine, of loss of the use of the lower limbs, and of injury of the pelvis, as well as in fractures, that one or more ought, in my opinion, to be placed in every permanent hospital in the British dominions. There is one now in use in the Westminster Hospital, and it has been the comfort and happiness, as well as the saving of more than one person.

"The position of a fractured femur must be essentially of one kind, viz. straight; for it is impossible to keep a man's thigh in the bent position on the side, and himself in the same situation. No power that is likely to be employed can prevent his turning on his back, and the union, if it take place at all, must be at an angle. The bent position forwards, or on an inclined plane, is defective, inasmuch as the matter, which must necessarily be secreted in abundance, will gravitate backwards, in spite of every care to prevent it; and in many instances will form abscesses towards the pelvis instead of always running directly outwards by a fair and unobstructed opening. When a proper bedstead is used, a slightly inclined plane may be tried at a later period of time; and in some cases the body of the patient may be raised even to the erect position. This must be done with care; the object is to take off the action of the muscles inserted into the little trochanter which raise the upper end of the fractured bone upwards and outwards, an event which invariably takes place after amputation, as high as the middle of the thigh. In simple fractures position will do this; and the inclined plane, whether by splints or other machinery, will effect it very well; but as an inclined plane can rarely be used with advantage in gun-shot fractures, the rising end of bone must be kept in its place, principally by raising the body, or by proper and well-directed padding; and its inclination outwards must be met by a similar direction of the lower part of the limb. These advantages the army never hitherto have had. I am aware of the difficulty of carrying these bedsteads to the scene of action in a distant country; I am also aware of the expense; but feelings of humanity, and public gratitude towards our brave defenders, ought in this case to prevail over

considerations of economy. A bedstead with mattress, &c. complete, may be easily bought, packed, and conveyed to the most distant of our possessions, for ten pounds; and six of them may be carried upon a common cart to wheresoever they may be wanted. If a second inclined plane and another set of bedding are added to the box, it will cost thirteen pounds, and will answer for two fractures. The battle of Toulouse, out of 1242 wounded, gave 43 fractures of the thigh which we endeavoured to save, and this may be considered as the usual proportion which this class of injuries bears to the sum total of the wounded; and I should say that a corps of 10,000 men ought to be supplied with a reserve store of twenty of these double bedsteads, at an expense, perhaps, of 260*l*. In Spain and in France we had nothing of the kind; and many soldiers suffered intolerable torments that might have been greatly alleviated, and many lives were lost that might have been preserved.

In gun-shot fractures of the leg, as well as in those of the arm, the first thing to do is to remove splinters and extraneous bodies. The bone being larger than that of the arm, the splinters are often more numerous and larger, upon which depends the question of amputation. But supposing that question to be decided in the negative, they are to be treated in a similar manner, and the extraneous substances or comminuted parts must, as far as is possible, be removed. These fragments must not be removed all at once, or at several succeeding examinations. They cannot come away of themselves unless they are very small; incisions must therefore be made for their removal, before any quantity of new bone shall be formed round them. This is a difficult but interesting point of practice, and requires experience for its safe conduct. The removal of splinters is sometimes neglected from the great thickness of the muscles of the thigh, or from the wound having been on the inner aspect of the limb, and near the great blood-vessels, where the making a large incision incurs risk. The thickness of the muscles does not offer a sufficient reason for avoiding an incision; and if the situation of the bone on the outside of the thigh be clearly known, a little reflection will shew that it can be got at easily in that part, if it cannot in another. If splinters are not removed, they become incarcerated by new bone, and remain either to be removed by a subsequent more painful and hazardous operation, or to continue a source of irritation for life. This irritation is not long in killing a patient. [Here the lecturer exhibited several femora, affording examples of necrosis in various stages.]

Where a splinter of dead bone is locked

up in new bone, amputation does not always give relief, or save life, for independently of the hazard of this operation high in the thigh, the femur above the injury is not always sound. It may be suffering from irritation of its internal membranes, and the saw only adds a mechanical injury to the mischief already existing. The internal membrane dies, and a necrosis extends upwards sometimes as high as the small trochanter. Although this evil occurs most frequently after gun-shot fracture, it also sometimes takes place after amputation in ordinary cases; I therefore warn you against the old practice of scraping off the periosteum before sawing the bone. A practised surgeon may amputate a thigh in 70 or 80 seconds; but gentlemen must not think they can saw bones by intuition; it requires practice to make perfect, as in every other art. If you wish to saw living bones in an artist-like manner, buy a couple of broomsticks, and saw them by inches; after this try your hands on dead bones, and then you will be fit to act on living ones.

It is possible to save thighs fractured any where, except at their extremities, by attention to the directions I have given, if you have at hand all the necessary appliances of surgery; but if you have not, and the patient must be kept in a constant state of motion and irritation, it is better to cut off his thigh at first.

Splints for fractured thighs must be of three kinds, with proper pads:—1. Long Desault splints. 2. Amesbury's leg and thigh splints, to be used straight for the thigh. 3. Common solid wood and tin splints."

The double inclined plane has for seventy or eighty years been employed at this hospital in fractures of the lower limbs of almost every description. The old apparatus, which has been supplanted by the more elegant inventions of Mr. Amesbury, still exists in the lumber room of the establishment, and although rude in its construction, is formed upon the same principles as the most approved modern contrivances. The late Mr. Lynn was particularly eloquent in the praise of the ancient machinery which he had employed with eminent success from his youth. Mr. Guthrie's colleagues still continue the employment of the double inclined plane, and will not certainly concur with him in his preference of Desault's straight and painfully coercive splints.

The reporter has witnessed Mr. Guthrie's surgical bed in action, and is sorry he cannot concur in the eulogy which he has pronounced upon it. This bed or couch consists of an ordinary bed-

stead, with four strong posts. To the top of each post is affixed a pulley. A frame is placed over the patient (after the bed clothes are removed), and broad straps or bands are placed under him at certain distances, and buttoned to the frame. The ropes of the pulleys are then fixed to this frame, and the patient is raised towards the top of the bed. By this means the under parts of him are exposed, and may be dressed. The process, however, is a long one, and extremely painful, and Mr. Guthrie has not succeeded in inducing any one of his colleagues to adopt the use of it. On the contrary, they prefer a couch invented by Mr. W. P. Knox, of Jermyn-Street, the machinist employed by Mr. Guthrie. This couch, which the author has named "the revolving invalid bed," is really an admirable invention, and deserves to be generally known. By a very ingenious mechanical arrangement Mr. Knox has enabled a patient to be moved in a great variety of directions, without any effort or movement of the patient himself. The machine is now employed in the Ordnance hospitals, in St. Thomas's, the Westminster, and some others, and has been found a great alleviator of pain. The following purposes are answered by its use:—

By the revolving motion the patient may have the pressure removed from one point of gravitation to another, in the direction of any radius from the vertical axis of his body, without the exertion of a single muscle by himself. Thus all the evacuations of the patient are made conveniently, and free from effort, the dressing of wounds and sores is facilitated, and the *enui* of uniform position is avoided. By the addition of a few contrivances to the revolving principle, the head of the occupier may be raised to a variety of different elevations; a double inclined plane is adapted either to one or both lower limbs; and a fracture apparatus suited to the superior extremities may be added. In bed sores the reporter considers it superior to Dr. Arnott's hydrostatic bed, which, from the great heat which it produces, by the suppression of transpiration, is not long tolerable by the patient. No such inconvenience, it must be obvious from the description, can attend the use of the couch now spoken of. The writer thinks that every private practitioner will be glad of the opportunity which Mr. Knox willingly affords of inspecting it; and afterwards of applying it to the alleviation of some of those melancholy cases of long-suffering which the lot of humanity too often presents. From the compactness of Mr. Knox's bed, it is capable of being converted into an ornamental piece of furniture. IDROS.

GLASGOW EYE INFIRMARY.

CLINICAL LECTURES BY DR. MACKENZIE.

September 22nd, 1833.

Iritis Sympathetica.

I AM about to direct your attention to a disease of the eye, of which we have had numerous cases under our care in this infirmary, and which my colleagues and I have been in the habit of distinguishing by the name of *iritis sympathetica*. It is a very serious disease; indeed, it has generally proved, in the long run, intractable in our hands; and, as it follows, and is in fact the result in the one eye, of a previous mechanical injury, which has already greatly impaired or destroyed the other, the undertaking of the treatment of it involves a heavy responsibility on the part of the practitioner. Whenever I see sympathetic iritis, even in its first stage, I know that I have to contend with an affection, which, however slight its present symptoms, is probably the most dangerous inflammatory disease to which the organ of vision is exposed.

The general nature of the sympathetic affection, which I am about to illustrate by references to our case-book, is inflammation, not of the iris only, but involving more or less the whole of the internal textures of the eyeball, especially the crystalline and vitreous capsules and the retina; coming on, generally, in five or six weeks after a lacerated wound of the opposite eye, and terminating, most frequently, in atrophy and total amaurosis of the eye secondarily attacked. The one, also, which received the original injury, generally ends, or has already ended, in an amaurosis and softening of the globe.

CASE I.—We have an example, then, of this sympathetic ophthalmia in David Mill (No. 8766), one of our present in-patients. He is 38 years of age, an engineer, and was admitted on the 30th of August, 1838.

When residing in Edinburgh, eighteen months ago, and whilst chipping iron, a splinter entered right eye, at outer edge of cornea. He continued to work for six weeks with his right eye tied up, when the left eye beginning to inflame, he gave up working. About two months after receiving the injury, a swelling formed over the wounded part, which being cut off, the foreign body, he says, was extracted. The right pupil is dragged towards the cicatrice; the nasal part of the iris is on the stretch; the capsule of the lens is opaque; the iris is close to the cornea, and is pretty natural in colour. The eyeball

is of the healthy consistence, and the cornea not more flexible than natural. No pain in right eye. With this eye discerns the fingers indistinctly, and sees a pen as a long stalk. Thinks vision of right eye improving.

About a fortnight before the piece of iron was extracted from right eye, the left began to be inflamed, and has suffered severely from iritis sympathetica. The iris is greenish; the pupil is nearly natural in size, but is mis-shapen, with its edge jagged, and fixed by adhesions to the capsule. Within the verge of the pupil the capsule presents a whitish wreath, without any red vessels. The whole of the lens is hazy, and of a greenish hue; consistence of eye natural: with this eye knows the infirmary card to be printed, and reads a type about three quarters of an inch in size.

Was at first affected with severe nocturnal circumorbital pain, for which he applied leeches, but was not bled at the arm. His mouth was made sore with mercury, which relieved the pain and improved his sight. Left eye has been pretty free from redness till within four or five months ago. Within last month its power of vision has declined, for at that period he could read an ordinary type. Pulse 84; thirst; appetite deficient.

A pill, every night, containing two grs. calomel and gr. ss. opium. Belladonna collyrium.

31st.—Has had no eruption on his skin. This question was put, with reference chiefly to syphilis; as in a previous case of sympathetic iritis, which we had here, there was some reason to suspect a syphilitic complication.

Sept. 4th.—Complains more of photopsia in both eyes, with occasional headache. Less thirst; appetite improved; bowels rather confined.

Castor oil, $\mathfrak{z}\text{j}$.

5th.—Still complains of flashes of light in both eyes.

Blisters behind ears.

6th.—Vision of both eyes, he thinks, improved; mouth sore.

Pill omitted.

7th.—Alum gargle.

8th.—Castor oil repeated.

11th.—Three leeches to nasal angle of left eye.

18th.—Complains more of pain in left eye; bowels rather costive.

Castor oil repeated.

19th.—Left eye relieved.

To take 20 drops, thrice a day, of a solution of 15 grains Morias Barytas in $\mathfrak{z}\text{ss}$. Tinct. Cinchonæ.

20th.—Thinks vision of right eye somewhat improved since his admission. Sees the large letters which he read at his admission plainer. No visible change in either eye.

Of the other cases of sympathetic iritis which I mean to bring before you, it will, in general, be unnecessary to quote the whole details of the treatment. These you can ascertain, if you think it proper, by referring to the journals.

CASE II.—Henry Paterson (No. 1010), aged 25, admitted 31st January, 1827. Two months before his admission struck the left eye against a nail which stood out from a door post. The upper part of the iris is no longer in view, so that the pupil is much enlarged, and shifted to behind upper edge of cornea. Severe inflammation has followed the accident, and has communicated itself also to the right eye, which, indeed, suffers more at present than the left. Both eyes exceedingly irritable on exposure to light, and affected with profuse epiphora. The right pupil small; both irides greenish, and both corneæ hazy. Retains a degree of vision in left eye; bowels very bound. Leeches have been applied frequently to the temples.

On the 7th February he is reported as improving, but very slowly. The treatment consisted in an emetic, followed by calomel, opium, and tartrate of antimony, with blisters, belladonna externally, and solution of nitrate of silver to the eyes.

We find from the subsequent reports, that his mouth becomes sore, and the pain diminishes. Afterwards the tenderness of both eyes increases and diminishes alternately.

On the 6th April he is stated not to have improved for the previous fortnight. On the 16th his mouth is sore, and his eyes decidedly improved. On the 30th, month well; inflammation continues to decline; vision of right eye very much better.

On the 11th May, left lens is mentioned as in an opaque state, and pressing the iris into contact with the cornea. After this, paracentesis corneæ was twice performed, but with little or no relief.

About the middle of June, the irritability of the eyes diminishes. This symptom had continued in a very distressing degree; but on the 11th July, the report states, that he can now open his eyes, which he attributed very much to steaming them with laudanum. On the 20th, intolerance of light much abated, so that the right pupil can now be observed contracted, and filled with a fibrinous effusion.

15th Aug.—Can now distinguish objects of moderate size. Inflammation and intolerance of light continue to decline.

This improvement took place under the continued use of calomel and opium, and a decoction of elm bark.

17th Sept.—Inflammation now gone; vision improves slowly. Centre of right anterior capsule opaque. Pupil somewhat contracted and adherent.

16th Nov.—Right pupil as at last report. Vision considerably improved.

25th Feb. 1828.—Vision improving.

During these twelve months, a great variety of remedies was employed. The principal were: 1, leeches; 2, scarifications of the eyelids; 3, paracentesis corneæ; 4, blisters; 5, tartar emetic eruption; 6, a caustic issue; 7, purgatives; 8, calomel and opium; 9, cinchona; 10, elm bark; 11, belladonna externally; 12, solution of nitrate of silver, and vinum opii, to the eyes; 13, anodyne fomentations; 14, red precipitate salve. Whatever benefit arose from the treatment, was to be ascribed chiefly to the 1st, 8th, and 13th of these remedies.

We saw nothing more of Paterson till the 8th September, 1830, when he was re-admitted, (No. 3011) for the purpose of having an artificial pupil formed in his right eye.

The report, at his re-admission, states, that his right pupil continues very small, irregular, filled with lymph, and attached to the capsule. Within last twelve months his vision has greatly declined, so that when his back is turned to the light he can discern merely the reflection from the face of a person standing before him. The iris is of a green colour, but there is no vascularity on the surface of the eye. Says that upon catching cold, the eyes are apt to become tender.

On the 19th, I performed the operation of incision with Mannoir's scissors. I need not describe the operation, nor dwell on the difficulties with which it was attended. These are set down at full length in the case-book. Any hopes of a restoration to sight by the operation were destroyed, in consequence of a blow which our unfortunate patient received on the right eye from a person in liquor, on the 28th March, 1831, which filled the aqueous chambers with blood, and completed the disorganization of the eye.

CASE III.—Joseph Moore (No. 5947), aged 30, was admitted 14th Dec., 1834.

About three months ago the right cornea was cut by a chip of cast-iron. Some portion of the humours escaped. Violent inflammation followed, which has terminated in discolouration of the iris, and coarctation of the pupil to a mere point, which is occupied by opaque capsule. Complete extinction even of perception of light in this eye.

About a month after the accident, the pain, which was at first chiefly confined to the right orbit, extended to the left. Since that time he has had symptoms of iritis inflammation in left eye. The iris is discoloured; the pupil irregular, contracted, not affected by light, and occupied by opaque capsule, apparently adherent to margin of iris. The opacity is less dense in the centre. With this eye he can still distinguish the bars of the window, and count the fingers interposed between him and the window. Occasional circumorbital pain over both eyes. Severe pain in bulb of left eye, especially at night.

Has been bled, and used some mercurial preparation, with temporary and partial benefit.

He was bled at the arm, leeches were applied to left conjunctiva, belladonna extract was smeared round the eyes, and he was ordered a pill, morning and evening, containing calomel, opium, and belladonna leaf, of each 1 grain.

Under this treatment vision improved slowly, but he still complained of pain in the balls of his eyes. Two grains of belladonna leaf were substituted for one grain. His mouth became sore, and the pain was relieved. It soon returned, however, and seems to have been but slightly alleviated by opium and belladonna internally, which made up the chief part of the treatment during January.

On the 5th February the report states, that considerable improvement had taken place in the vision of the left eye. Gentian, and afterwards quina, appear to have been employed on account of general weakness. No further improvement is noticed.

CASE IV.—James Downie (No. 7538), aged 25, was admitted 5th January, 1837.

About three months ago his right eye was wounded by a splinter of steel. It now presents a cicatrice at the junction of the cornea and scleroticæ, towards nasal side of eye. The pupil is dragged towards the cicatrice, while the iris opposite to it appears on the stretch. There is some opacity towards lower part of pupil. No pain. Vision of right eye much impaired.

About seven weeks ago the left eye became affected. The iris is now discoloured; the pupil contracted and irregular. The form of the eye is disfigured, the anterior part being projected. The conjunctival vessels are red, and there is a bluish zone around the cornea. Does not complain much of pain in the eye: its vision seems nearly extinct.

Has been bled, blistered, and mercurialized, and had improved considerably, but having gone to the country about ten days ago, became much worse.

Leeches were applied to the left upper eyelid, and a blister behind the ear. Calomel and opium were prescribed, and Dover's powder at bed time. These remedies were continued, along with repeated leeching, and the external use of belladonna, during the month of January, with little or no effect on the state of the eyes. On the 1st February the report states, that, with his back turned to the light, he distinguishes objects with the right eye, but not with the left. He is put on a solution of hydriodate of potass, $\text{Sij. to } \text{ʒviij.}$ of water, a table-spoonful thrice a day; and the quantity of the hydriodate is increased gradually to ʒiv. There is no notice of any improvement; but, on the contrary, the surface of the iris is stated to have become vascular—a very unpromising symptom; and on the 16th he is ordered to be bled at the arm, on account of increased inflammation of left eye. His mouth does not appear to have become sore. The bleeding at the arm relieves the pain of left eye. On account of costiveness, the calomel and opium pills are changed for blue pills. On the 22nd, his mouth is pretty sore, but there is no improvement in vision, and the irides are described as assuming a gilt green colour. He now complains of want of sleep, and is ordered opium and sarsaparilla. This last medicine appears to have been continued for nearly two months, but without benefit. On the 22nd of April, the sarsaparilla is discontinued, and he is ordered one-sixteenth of a grain of oxide of arsenic thrice a day. On the 6th May the report states, that there is no change. The outer margin of each iris is occupied by a lavender-coloured ring. The left pupil is contracted, and occupied by opaque capsule.

CASE V.—Robert Finlay (No. 7873), aged 21, was admitted 5th July, 1837. Last night the right cornea was penetrated by a screw-driver, so as to form an angular flap, with the apex pointing downwards and inwards, while the extremities of the incision are separated by a space equal to the diameter of the cornea. Much blood is effused into the anterior chamber. The iris appears to be wounded; the state of the pupil cannot be discovered. Vision with this eye is reduced to a mere perception of light. The eyelids were brought together, and a bandage applied.

V.S. Six grains of calomel.

6th.—Pain relieved. As the calomel had not purged, he was ordered three aloes and blue pills.

On the 1st August, the wound is said to be cicatrized; pupil very irregular; considerable vascularity of eye; little pain.

A blister behind right ear. Muriatis Hydrargyri Collyrium.

5th.—Eye less vascular; lids adhere in the morning.

Four-grain solution of Nitræ Argenti.

Leeches were after this applied twice to the eye-lids.

On the 13th we find the following report:—Since yesterday an attack of iritis sympathetica of left eye, with pain beneath the eye-brow during the night. Upper edge of pupil appears tagged to capsule. Ascribes this attack to having read a book, in small type, for three or four hours last night. Pulse 84.

V.S. Belladonna to left eye-brow and upper eye lid. Six grains of calomel, and one grain of opium, at bed-time. An ounce of Sulphas Magnesiae to-morrow morning.

14th.—Blood buffy; pain greatly relieved; cornea flexible; pupil tagged above and below.

Eight leeches round left eye. Belladonna repeated. Calomel and opium at bed-time, and salts to-morrow morning.

15th.—Pupil transversely oblong; vision very dim.

V.S. Blister to left side of head. Four grains of calomel, and half a grain of opium, thrice a day.

16th.—Blood buffy.

17th.—Pain of left eye entirely gone; pupil still irregular; mouth not affected; tenesmus.

Castor oil, \frac{ssj} . Calomel and opium continued.

18th.—V.S.

19th.—Blood buffy; eye much less vascular; vision clearer.

20th.—Cornea less flexible.

21st.—Castor oil repeated.

23d.—Pupil more regular; eye free of vascularity.

24th.—Two grains of calomel, and a quarter of a grain of opium, daily.

27th.—Mouth sore.

Calomel and opium omitted.

31st.—One grain of Sulphas quinae thrice a day.

Sept. 1st.—Lower part of pupil more regular.

3d.—Sulphas magnesiae, \frac{ssj} .

4th.—Very numerous and minute whitish spots, apparently on the inner surface of left cornea, opposite lower edge of pupil.

Belladonna omitted.

Sulphas magnesiae repeated on the 7th; and 8th, calomel and opium renewed.

12th.—As the pupil contracts from the omission of the belladonna, vision becomes dimmer.

Calomel and opium morning and evening.

On the 15th, vision clearer. He had sulphate of magnesia on the 13th, 14th, 19th, 24th, and 25th.

On the 26th the calomel and opium were stopped.

27th.—One grain of opium. Alum gargle.

29th.—No pain in right eye unless when pressed with the hand. The minute spots on inside of left cornea still very numerous. With this eye reads a very large type.

Two grains of extract of stramonium morning and evening.

Oct. 5th.—Was attacked last night with violent pain in both eyes. At present the pain affects principally the left eye.

V.S. To foment the eyes with poppy decoction.

6th.—Left conjunctiva this morning in a highly chemosed state.

V.S. Four grains of calomel and one grain of opium at bed-time, and half these quantities in the morning.

7th.—A much better night; inflammation greatly abated.

10th.—A recurrence of severe pain this morning. Leeches; fomentation.

13th.—Has again had a smart attack of pain. Pulse 84, feeble; fomentation.

14th.—Mouth sore. Calomel and opium omitted. Alum gargle; blister behind left ear.

16th.—No pain in eye; mouth better.

18th.—Another attack of pain this morning. Five leeches; fomentation.

21st.—Has continued easy since the application of the leeches.

25th.—This forenoon was again seized with pain, which is accompanied this morning with vomiting. Four leeches; fomentation.

Nov. 8th.—Has continued free from pain since last report.

10th.—Some pain in right eye. Two leeches. Two grains of calomel and half a grain of opium at bed-time.

Dec. 10th.—At present the right eye is entirely free of inflammation. Its cornea is bounded by an irregular line, and is reduced to half of its original size. Distinct perception of light and shadow with this eye. The cornea of left eye is now unnaturally prominent, and surrounded by a

reddish zone. The iris is greatly altered in colour, and is bulging forwards, so as to be very nearly in contact with the cornea. The pupillary margin seems to be adhering to the capsule, which is opaque in the centre. The perception of light is less even than in right eye. Some palpitation for four or five weeks; pulse 110, rather sharp.

CASE VI.—Jane Gartshore, (No. 8455) aged fifteen years, admitted 30th April, 1838.

Six months ago, left cornea was divided, towards its outer edge, by being struck against the latch of a door. The iris had protruded, as it is now dragged towards the site of the wound, and fixed there. What remains of the pupil is occupied by opaque capsule. Large varicose vessels run towards the cicatrix. There are also numerous vessels on the surface of the iris. This eye retains the perception of light and shadow.

Four or five weeks after the injury, sympathetic iritis came on in right eye, and the vision of this eye, also, is now reduced to a perception of light and shadow. The right iris is of a dingy green colour, with numerous varicose vessels running over it. The pupil is contracted, irregular, and adherent to an opaque capsule. Both irides are close to the cornea.

Has now no pain. It was severe in the left eye, for nearly four months; but the right eye, she says, has never been affected with pain. General health was previously good. Pulse 120. Was twice bled at the arm; applied leeches and blisters, and took some medicine, which did not affect her mouth. Two grains of calomel and half a grain of opium thrice a day.

May 7th.—Thinks her vision improved.

Such are some of the cases on our books, serving to illustrate the fact, that the one eye sympathizes strongly with the other, when the latter has suffered from mechanical injuries of certain of its textures. The conclusions which these cases, as well as others recorded by different authors, warrant us in drawing respecting this sympathetic ophthalmitis, I shall endeavour to arrange and lay before you next Saturday. In the meantime I may refer you to two authors, whose works ought to be in the hands of you all. You will find it stated by Mr. Wardrop, (*Morbid Anatomy of the Human Eye*, vol. ii., p. 36), that when inflammation is excited in the iris of one eye, it sometimes happens that the iris of the other eye is in like manner affected. He notices an instance, in which the iris of one eye being inflamed in consequence of a punctured wound, the same

disease soon afterwards attacked the other eye; and at page 116 of his first volume, he mentions the case of a person, who having received a blow with a pike on one eye, which produced staphyloma, the other eye, more than a year afterwards, inflamed, and gradually became staphylomatous likewise. At page 147 of Mr. Lawrence's *Treatise on the Diseases of the Eye*, you will find it stated, that "when an eye has been lost by accident, the other often becomes diseased sooner or later, without any imprudence, or any external influence that would be injurious under ordinary circumstances. This kind of occurrence is so common," says Mr. Lawrence, "that it is necessary to warn those who have lost an eye of this danger." Six cases are given in illustration.

ST. BARTHOLOMEW'S HOSPITAL.

CASE OF HYDROPHOBIA.

To the Editor of the Medical Gazette.

SIR,

If you should consider the particulars of the following case of sufficient interest for insertion in your journal, they are at your disposal.

I am, sir,

Your obedient servant,

JAMES WM. FLOTT,

House Surgeon, St. Bartholomew's Hospital.
September 29. 1838.

Ann Jameson, æt. 53, residing at Bromley, in Kent, was bitten on the back of the right hand and fingers by a terrier, supposed to be mad, on Sunday, July 22nd, 1838. Shortly after the infliction of the wound the parts were excised and cauterized, and soon perfectly healed. She, however, afterwards occasionally complained of slight uneasiness in the hand—a circumstance attributed by her friends to fancy, as she was a good deal frightened about herself. On Monday, the 24th of September, she complained of considerable pain in the hand, running up the arm, and also of a sensation which she describes as being like the pricking of pins or needles, whenever she draws her left hand across the arm, or extends the fingers. On examination, the cicatrices and parts adjacent appear in a quiet state. There is, however, a slight tumefaction on the back of the hand, near to one of the wounds, but not in the course of the absorbents. At this time there was no other symptom.

25th.—During the night she was attacked by spasms in different parts of the body; more particularly in the muscles employed in deglutition. The spasms are

evidently excited by the presence of liquids; and, on attempting to swallow water or any other fluids, or indeed solids, are much increased.

Afternoon.—The spasms are as frequent, but not so violent, but are much aggravated by the attempts to swallow fluids. The countenance is calm in the intervals of the spasms.

26th.—Has passed a very restless night. She has never slept since the commencement of the attack. About two o'clock she brought up a considerable quantity of dark slimy mucus. The vomiting continues, and is now almost incessant, with much straining. The matter ejected she says is very bitter. The hydrophobic spasms have somewhat abated since the vomiting came on, and she is now able to swallow fluids without much difficulty; but they are almost immediately rejected.

Afternoon.—The vomiting of the dark-coloured matter has ceased, but the sickness continues, with a constant spitting of large quantities of white frothy phlegm. She says that the only pain she feels is in the throat. The countenance is much distressed, and she is very restless, and sighs frequently. The pulse, up to the present time, had been regular, but is now accelerated. The tongue white, but not coated. The sensorium somewhat affected, as she talks incoherently at times, but answers rationally any question put to her.

Evening.—She has fainted two or three times, having at the same time slight convulsive twitchings, which lasted for some minutes. These convulsive attacks increased in strength and duration, and at twelve o'clock she died.

The treatment consisted principally in the administration of opium and ammonia. The following were the appearances I observed on making a post-mortem examination, commencing with the spinal cord, the membranes of which, more particularly the arachnoids, were found considerably inflamed. The cord itself was healthy, but perhaps a little softer than usual. Brain and its membranes healthy, with the exception of some ossific deposits in the falciform process of the dura mater, and some serous effusion in the choroid plexus of the left side. Mucous membrane of the pharynx, and upper part of the œsophagus, as likewise of the stomach, more particularly at its pyloric extremity, inflamed. The reddening of the membrane of the œsophagus terminated somewhat abruptly at its upper part. There were several darker spots in the stomach, apparently from the ecchymosis of blood in those situations. All the other viscera of the body were healthy.

The above case, I think, presents two or

three interesting points of observation, and, firstly, as shewing that the measure on which certainly the most reliance is to be placed in the prevention of this truly formidable disease, namely, careful excision and cauterization of the parts, will not always succeed, although done shortly after the reception of the injury; and again, with regard to the influence that the mind may have in exciting the disease. The same dog that bit this woman had attacked and bitten other persons, one the servant of a gentleman in the neighbourhood. He had been bitten in the hand a short time before the woman was attacked. The same measures were adopted as in her case; but since then, at least up to the present time, he has remained free from apprehension; she, on the contrary, has always been more or less alarmed about herself. In this, then, as in many other affections, the state of mind must be considered as having something to do among the predisposing causes of disease, those being less liable to be attacked who fear it least. There is, I think, another point in the case worthy of remark, namely, the partial subsidence of the hydrophobic spasms after the violent vomiting which occurred.

SPLINTS USED AT UNIVERSITY HOSPITAL.

To the Editor of the Medical Gazette.

SIR,

IN the absence of Mr. Keyser, allow me to point out an error in the letter of your correspondent, Mr. Hancock, who makes the former gentleman to have said, "that no such splint as Mr. Amesbury's is employed in the North London Hospital;" whereas the words were, that "the splint represented is not that of Mr. Amesbury; nor is any such splint employed in the treatment of fractures of the thigh at this hospital."

The readers of your journal will not fail to observe a wide difference between the words actually used, and the representation given of them by Mr. Hancock.

The name of the splint here called "Liston's," is of little consequence; the splint itself is a modification of M'Intyre's, constructed under the direction of Mr. Liston, and possessing these important advantages over the original, and also over that of Mr. Amesbury—that it is more simple in construction, more easy to the patient, and less expensive in cost; the first and last of which advantages have been done away with by your correspondent, Mr. Hancock, who has thus succeeded in complicating a single apparatus, for the

sake of employing it for purposes to which it was never intended to be applied, and for which may be used means much more simple and efficient.

With regard to the integrity of Mr. Liston, of course neither Mr. Keyser nor myself have any intention of impeaching it; but I would ask of Mr. Hancock whether a non-professional person, an artist, would be more likely to know if a fracture, adjusted upon a certain apparatus, was one of the leg or the thigh, than the house-surgeon, who probably reduced it, and effected its adjustment himself.

I am, sir,
Your obedient servant,
J. DERANCE GEORGE,
House-Surgeon.

University College Hospital,

SINGULAR INSTANCE OF ATTENUATION.

THE following singular instance of attenuation is extracted from Urquhart's *Travels in the East*, and is curious in a physiological point of view:—

“In passing through a village, I was struck with the sight of a stiff and shrivelled corpse, clothed and seated in a chair, laid slanting against a wall, so that the feet were in the air, and the head was bent down upon the breast. While I was looking at it, I was startled by a jerking motion in the right arm, and then seeing two black and vivid eyes straining to catch my attention. This was a human and a living being, which had existed in this shrivelled and motionless state for 28 years; the flesh seemed to have disappeared from his bones; the skin had shrunk, and was almost black: I have seen mummies that appeared in a better state of preservation. The joints were all fixed, with the exception of the right shoulder and the jaws. This freedom of the shoulders amounts, however, only to three inches of a see-saw movement of the forearm, and he keeps working it backwards and forwards, as he says, *for exercise*.”

NUMBER OF MEDICAL MEN IN GREECE.

In 1837, Greece contained upwards of 926,000 souls: the army amounted to about 12,500, and the navy consisted of 32 vessels of war. The entire number of licensed practitioners, exclusive of the medical men belonging to the army, was 85; but there were no fewer than 130 empirics, who are tolerated by the government, in consequence of the lack of educated practitioners.

LECTURES ON SURGERY,

DELIVERED AT ST. THOMAS'S
HOSPITAL,

BY THE LATE MR. CLINE;

With Notes.

[THESE lectures were written by Dr. Wilkinson when attending Mr. Cline's lectures, in the years 1787-88-89.

Extract of a letter from Dr. Wilkinson, dated Feb. 6, 1838:—"They (these lectures) are the results of six courses of lectures I attended at St. Thomas's, in 1787, 1788, and 1789; and I am in hopes I did not omit any interesting part of Mr. Cline's valuable observations. The one I had the pleasure of giving you is the repeatedly corrected copy."]

LECTURE III.

Observations on Cancer — Extirpation of the Mamma — Fistula Lachrymalis; different modes of relieving it by operation — Cataract, Couching, and Extraction of the Lens — Operations on the Iris — Extirpation of the Eyeball.

Amputation of the female breast.—This operation is generally performed on account of a scirrhus affection of the breast, which terminates in a truly cancerous ulcer, provided the process of the disease is not stopped. Before we proceed to the operation, it will be necessary to say something respecting the progress of this disease. It usually begins with a small tumor, which increases very gradually; and gradually, as it is increasing, a greater portion of the glandular part of the breast becomes hardened in the same way. One very striking characteristic of the disease is, that of its not terminating in a circumscribed edge, like other encysted tumors. You find a very gradual diminution of the

hardness, so that you cannot tell by the feel where it terminates. There is rather a sensation of numbness than pain, in the beginning. The disease gradually advances, and as it increases in size it approaches nearer the surface; when it arrives near which, the skin adheres to it, so that it loses its motion; soon after this it takes on a purplish red colour, when we find the surrounding superficial veins become enlarged and tortuous in their course, supposed to resemble the claws of a crab—whence it has been called cancer. This occurs not in cancer only; but wherever there is an increased circulation in a part the veins become proportionably enlarged. Then discolouration of the integuments takes place, at which time the tumor usually becomes more painful than before; soon afterwards some small ulcerations take place about some part of the surface, usually about the middle of the purple part, and a little bloody serum is discharged. As soon as it is opened the pain becomes more considerable and constant, burning lancinating pains extending to the arm, so that the patient gets but little rest. The discharge, which is a mixture of serum and blood, gradually increases; the wound usually becomes very offensive, and the patient is gradually worn out by the pain and discharge; and what further contributes to hasten this is, that as the varicose veins become frequently ulcerated, and their coats destroyed, very profuse hæmorrhages often occur. Besides this diseased affection of the contiguous parts taking place, we find other textures which are deeper seated become affected, as the pectoral muscle, to which, as the tumor increases in size, it adheres; to ascertain this, put the muscles on the stretch, and if the tumor adheres it will not be moveable. Also, the contiguous lymphatic glands gradually partake of the disease. When the tumor becomes painful, soon

after there is usually pain in the axilla; and when examined, the lymphatic glands are found enlarged; sometimes only one or two may be felt, whilst at others times there are clusters of them. This disease originates at one small part of the glandular substance of the breast in general, and gradually contaminates the rest by extending to all the contiguous parts. The lymphatic glands become diseased from some absorption of the fluid situated within the parts, which being constantly carried to the lymphatic glands, eventually affects them, but more particularly the glands where the fluid is deposited first. This disease usually arises spontaneously without any evident known cause, and most frequently in women between 40 and 50, usually about the cessation of menstruation. Generally at this time the glandular substance becomes less. About the time when their menstruation becomes irregular, and does not observe its periods and quantities as usual, then they are very subject to the formation of these hard tumors in the breast, which in some make more rapid progress than in others; in some a large portion of the substance of the breast becomes diseased, in others it begins at one part only. I have seen some where it has begun in the whole substance at once. Every now and then it arises from injuries of the part, as blows, and that at almost any period of life. With careful attention, many of these, especially those arising from injuries, may be removed at first, by evacuations, local bleeding, &c. If these do not remove the complaint, it will be necessary to adopt a course of medicine, which is of long continuance. Cicuta has been recommended in these instances, and I have given it in considerable doses, such as two, three, or four drachms daily; it alleviates the pain, but is not attended with much advantage. Soon after the medicine is left off the tumor again becomes painful, and increases. In some instances I have known electricity succeed, by passing small shocks through the parts; and in some, small doses of mercury have entirely removed it. In some few instances I have known emetics succeed, but have found nothing so successful as martial flowers*, continued for a great length of time, as much as the stomach can bear, in the form of pills, beginning with about five grains, and gradually increasing it. This should be continued many months, sometimes more than a twelvemonth. We find it remove

the pain, which returns if it be left off; therefore it should be continued a long time after the patient is well. However, there are many cases which this medicine will not benefit, especially such as arise spontaneously. In some few cases I have known it remove them, though rarely. However, during the exhibition of these medicines, the tumor should be carefully examined from time to time; for if we should find it increase in size we ought speedily to recommend the operation, for the sooner this is performed, the more certain we are of success, as it is a disease which, when arrived to a certain extent, cannot be removed by any means. For instance, though the tumor is but of a moderate size, and attended with very inconsiderable pain, the glands in the axilla often become affected, even at a time when they do not appear to be so at all, or only one seems enlarged; yet after the operation, you find a cluster of glands diseased, extending along the axillary artery under the clavicle. The great mischief of delay in these cases is, that the disease is extending along the axilla often much sooner than we expect. If the patient is not receiving any benefit, the operation should be recommended, in which we should not aim at removing the diseased portion only, but a large portion of the surrounding parts, as the contamination often extends much further than we expect; otherwise we may have a return of the disease. If the disease has advanced so far as the glands of the axilla, the operation is objected to; also when the tumor is no longer moveable on the pectoral muscle, or is firmly adhering to the cartilages of the ribs. It is a question with some, whether this disease is at all times entirely local; whether it does not frequently become constitutional; whether, by passing into the circulation, it does not contaminate other distant parts; but from the numerous instances I have seen of this disease, I have reason to believe that it never contaminates any parts except those which it can come at immediately, without being carried through the circulation: so far as the absorbent vessels pass, so far will the disease extend, and no further. The viscera become affected in consequence of some cancerous affections, as in the testes; but still this is in the course of absorption. This seems to be a poison which loses its effect as it gets into the circulation. When, then, the disease is perfectly circumscribed, and confined to the glandular substance of the breast, and there is no reason for suspecting particular adhesions and enlargements of the glands, the operation may be at all times advised, and that with the greatest probability of success. It is very

* Flores Martiales. — They are thus prepared:—"Take, of washed colcothar, or green vitriol, or of iron filings, 1 lb.; of sal ammoniac, 2 lbs.; mix them, and sublime them in a retort; and mixing the bottom again with the flowers, renew the sublimation till the flowers acquire a beautiful yellow colour."—*Rees' Encyc.*—C.

simple, only dissecting out the diseased part; a larger knife than a common dissecting knife will be most convenient, as, having a broader surface, it cuts more at a time, and the operation is sooner finished. It is most conveniently done by placing the patient in a chair opposite the surgeon. Where much of the breast is not diseased, a simple circular or oval incision through the integuments will be sufficient. Generally, when the tumor becomes large, it adheres in some degree to the integuments, which, partaking of the disease, ought to be removed. In taking out the tumor a large portion of the surrounding adips should be removed. If any lymphatic gland is found enlarged, it should be taken away if possible. Very frequently we find the surrounding adipose membrane has a harder feel than usual; in this case it is better to dissect away more of it, for it is probably owing to a diseased deposition taking place in the part.

When the whole of the diseased part is removed, the integuments may be brought together, and united by adhesive plaster. Very frequently some vessels are wounded, which should be secured by ligature, and that as early as possible. During the time of the operation the patient generally becomes faint, and has a languid circulation, which gives the extremities of the divided vessels an opportunity to contract. Some time after being put to bed, the circulation returning, the hæmorrhage is renewed, by the mouths of the vessels opening again. Tying the vessels may be either done with a needle and ligature, or by means of a tenaculum. We take a curved needle, include the extremity of the artery, and pass it through on one side, at a moderate distance; it is then to be brought back again on the opposite side; then making a knot on the part, this goes completely round and includes the artery. This is sometimes a very troublesome operation, for the arteries are often in such a situation that you cannot conveniently come at them; and the nerves are frequently so near, that, while you are securing the one, you are in much danger of wounding the other; on which account, and as giving less pain, many prefer the tenaculum, which is passed through the extremity of the vessel, and the ligature tied round it, without any needle being passed through the muscles or any of the contiguous parts. In the tenaculum there are certain disadvantages:—1. There is some danger of tearing the artery by passing the tenaculum through the vessel, and if so you have difficulty in recovering it again. Also, the ligature having no further hold than on the vessel, it is frequently slipping off. There have been instances of the femoral

artery being very perfectly tied by means of a tenaculum, and the hæmorrhage has come on in a few hours after. Besides this, ulceration often goes through the coats of the vessels, on which account we are liable to have a return of the hæmorrhage; therefore I prefer the needle, except for small arteries situated in cellular membrane, and here the tenaculum, or forceps, may be used. It is not always necessary to pass the needle twice, as passing it once obliquely round small vessels may frequently be sufficient. The drawing out of the artery with a tenaculum is sometimes impracticable; in this case it is just as easily done with a needle, and more securely.

In taking up vessels the ligatures should always be broad, that they may not ulcerate through the parts quickly*. Supposing in this way the hæmorrhage is stopped, sticking plaster, &c. applied, the patient is very soon well. But not unfrequently after this operation, though it has apparently been done in the best manner, and with all probability of success, still you are interrupted by a return of the complaint. If this is entirely in a circumscribed part, the operation may be performed a second time, securing a greater number of the surrounding vessels. It may and has been performed a third time with success. Sometimes the appearance of a return of the disease is manifest long before the wound is well. From this a fungus will gradually arise, followed by a fetid discharge. I have frequently known, where the whole breast has been removed, there has been a large granulating surface, going on healing, to the breadth of a shilling; an unhealthy appearance has arisen, with fungus, and the ulceration has proceeded to as great an extent as before the operation. In this case of incurable cancerous disease, whatever gives the most relief and ease is the best remedy. Opiates will be most proper, and the external application which I have found best is the carrot poultice, scraped fine and heated over the fire, which makes the wound easy, and the discharge less offensive. Under these circumstances, however, the disease goes on to be fatal.

Fistula lachrymalis.—This is a fistulous orifice, situated at the inner side of the orbit, which has a communication with the lachrymal sac, through which opening the tears are discharged; but the disease, which arises from an obstruction of the ductus ad nasum, has the name of *fistula lachrymalis* given to it long before a fis-

* This opinion is now exploded, and it is generally admitted that ligatures should be small in size and round in form. "Dentists' silk" is perhaps the best, as combining these properties with considerable strength.—C.

tulous orifice is formed. The first appearance of this disease is a little fulness at the inner side of the under eyelid, and the tears take a wrong course, passing down the cheek instead of going as usual into the nose. The lachrymal sac under such circumstances is distended, and constantly filled with tears, forming a small tumor in the eye; it will not receive any tears into the puncta, and the remainder pass over the cheek. This increased distension of the sac occasions inflammation, which produces adhesions of the parts, and the patient almost insensibly gets into the habit of pressing on the tumor, which gives some relief till it becomes again distended. There is a mixture of tears, mucus, and pus, which exudes from the puncta lachrymalia, on making pressure. After this has continued for some time, the skin covering the sac becomes inflamed, and soon ulcerates, which ulceration extends from the sac to the skin, making an opening externally, which no longer containing the tears, they pass down the cheek: this is the true fistula lachrymalis.

The cause of this disease is an obstruction of the ductus ad nasum, which being long continued, as happens frequently in scrofulous patients, gradually produces a thickening of the membrane, which remains after the disease has subsided. Sometimes, as in ulceration originating from venereal or other causes, venereal ulcers are forming in the nose, which may happen at the termination of the ductus ad nasum. In the same way it is sometimes produced by the small-pox pustules forming in the nose, which happening at the termination of the duct, will produce a small obliteration of the canal. Sometimes it occurs from a polypus forming at the part. From whatever cause the duct is obstructed, the effect will be the same. From this description of the disease it may be considered in three states:—First, Where there is a simple obstruction of the duct, which is only producing a distension of the sac. The second is, when it has extended to inflammation, as is ascertained from the discoloration of the skin; also from pus passing through the puncta lachrymalia when pressed upon. The third state is when ulceration has taken place, making an external opening, so that the tears, being no longer contained, pass down the cheek.

We shall now proceed to the treatment of the disease in these three different states. In the first stage an instrument for compressing the sac is recommended, to pass round the forehead, with a button to be placed on the sac, keeping it constantly pressed. I much doubt whether this instrument is attended with any ad-

vantage; it prevents an accumulation of tears within the lachrymal sac, and in that way may prevent inflammation taking place so soon; but not at all contributing to remove the cause, it will only protract the formation of the fistulous orifice. Some have proposed syringing the lachrymal sac for the purpose of removing the obstruction; and also, for abating the inflammation. Anel has contrived a very small syringe for the purpose, with an exceedingly small pipe, which he directs to be introduced into the puncta lachrymalia, and the sac syringed with some detergent fluid. Others have recommended a syringe with a curved pipe, to be introduced up the nose, and syringing in that way. This treatment may be considered rather as speculative than beneficial, and that by the puncta lachrymalia is not very practicable, for it is an extremely irritable part. The tunica conjunctiva is continued to the orifice of the puncta, which, when touched, produces considerable irritation and contraction of the eyelid. It might be more conveniently done by dropping a fluid into the eye; then closing the eyelids, having previously emptied the sac, it will get into the puncta very readily, and subsequently into the sac itself. To abate the inflammation fomentations have been frequently used, as taking in the steam of some warm fluid into the nose, which is applied in that way to the neighbouring parts. Some recommend sternutatory powders, but not with much advantage. If the inflammation arises from a venereal cause, which is sometimes the case, the use of mercurials will often remove it; but if from other causes, then the inflammation keeping up an obstruction to the tears, produces an accumulation in the sac. Sometimes the part cures itself by forming an opening through the skin, the tears thus flow out of the sac, and the distension is no longer continued. The inflammation of the sac being discontinued, the opening becomes again free, and the external orifice heals up. We therefore in many cases attempt this treatment chirurgically. When inflammation is taking place in the sac, it is advisable to make a small incision through the integuments, about half an inch in length into the sac, of an orbicular or semilunar form, that it may take the course of the muscle a little below the tendon of the orbicularis. The upper part of the sac is behind the tendon, but it is not necessary to open the sac throughout its whole length; therefore the wound of the tendon is unnecessary. This opening being made, a dossil of lint is to be laid into the sac to prevent its closing. The patient should be directed some hours before the operation not to make pressure on the part. Then a small bougie may be in-

troduced, and after a few days you can examine whether the ductus ad nasum is become sufficiently opened, when the external wound may be closed. But for the obstruction in the ductus ad nasum there will be a necessity for making an artificial opening into the nose, by perforating the *os unguis*. This may be done with a curved trocar, which should be directed inward, and a little obliquely downward, in which way the *os turbinatum superius* will be avoided, and the opening made between the two turbinated bones. An actual cautery has sometimes been used; this is an instrument not now found to be necessary; the orifice may be rendered completely fistulous without. The probe should be passed behind the nasal process of the *os unguis*, in which way you readily pass it, and you know whether the instrument has passed into the nose by some blood coming from the nostrils at the part. After this perforation is made through the *os unguis*, a piece of bougie, or some such substance, should be introduced into the nose, to prevent the external orifice from closing, and kept in for ten days or a fortnight, till suppuration takes place; then you may withdraw the tent, and close the external opening by adhesive plaster, bringing the sides of the wound in contact with each other. In these cases, where you cure the patient by making an opening through the skin externally, the cure is not radical, but only temporary; the disease is frequently returning, from time to time. I have known people plagued at times with this complaint for several years together. Mr. Warthen has introduced a mode of preventing the disease from returning, by introducing a canula of gold or silver into the duct, the canula being made a little larger at the upper part, to prevent it slipping down the nose. This has in many instances been successful; in others it has failed, and been very troublesome. Sometimes it has slipped into the nose. It is only practicable in those cases where you have the ductus ad nasum open; in all those cases where you have a diseased thickening of the membrane in consequence of inflammation, and not from the actual presence of existing inflammation, or in those cases where adhesions have taken place in the sides of the ductus ad nasum, you can only make a perforation into the sides of the nose. It has been common with some ancient surgeons (whom Mr. Pott justly reprobates) to treat the disease like other fistulous openings, by using escharotics to destroy the whole surface: by such the opening may be healed; but the tears very often take a wrong direction, passing over the cheeks instead of into the nose.

Couching, or the depression of the crystalline into the vitreous humor.—This operation is usually performed with a single instrument, the *couching needle*, generally of the shape of a myrtle leaf, flattened at the sides, and having two edges, which are gradually brought to a point. Some use a needle quite round. The needle is passed in at the outer part of the globe of the eye, about one-tenth of an inch behind the cornea transparens; in this way it passes through the opaque cornea, into the aqueous humour, then into the upper part of the crystalline: you place the flat part of the instrument over the cataract, (which you may know by some dots on the handle,) and press it down to the inferior part of the globe. The most convenient position for the patient is sitting in a chair opposite the surgeon. When the instrument is passed into the eye as far as the cataract you turn it. By looking at the pupil you at once discover whether you have depressed it, by observing the white speck below; and the patient is now immediately sensible of light coming to his eyes, and discovers objects. In doing this operation you are frequently embarrassed, which depends on two circumstances—one is, the adhesion of the capsule of the crystalline to the iris, which is an objection to the operation; another is, that of the cataract being in a fluid state; in which case, though you may very much disturb the humours of the eye, yet you have not such command over the lens as to remove it; but its being fluid is no objection to extraction, which may be done with equal success as when solid. Couching is certainly attended with more pain than extraction, the instrument passing through the choroid and retina, while in extraction, cutting through the cornea is no more painful than simple pressure of the globe. I have performed this operation on patients who have been twice couched, who affirmed the same on this point. Another inconvenience attending it is, that when you have performed the operation so as completely to depress the cataract, it often rises again, so that patients have had the operation repeated frequently. I have heard of this operation being performed five or six times on the same eye. It is attended with a good deal of inflammation, which so often repeated must greatly endanger the eye; it is sometimes so violent and goes to such an extent in the structure of the eye, so as to make an opening necessary for the discharge of the matter; consequently the structure of the eye must be destroyed. In this case we should guard against inflammation during the whole progress, with Aq. saturn.—Cataplasms. Pap. Alb. and local bleeding.

The operation ought only to be performed where both eyes are affected, as, if only one, the focal distance will be so different in each eye, as to render the inconvenience greater than before the operation.

Extraction of the cataract.—It is universally agreed that this disease never arises from films in the aqueous humour, but that it is an opacity in the crystalline lens which comes on gradually, till the lens is entirely opaque. Sometimes it is preceded by great pain; at other times, by none at all. The white speck in the pupil differs in different subjects, according to the degree of opacity which has taken place. Sometimes it is yellow, sometimes brown, and by degrees the whole of it becomes opaque; and at last the person is perfectly blind. Cataracts are of different colours; when they are white we call them milky, in which the crystalline humour seems to be dissolved, and when the needle is thrust into the eye, the fluid passes through the capsule and escapes. In this case the most likely manner of curing the disease is by extraction. The patient should be placed opposite to you in a lower chair than yourself; you rest your elbow on your knee, with the two last fingers on the temples of the patient; if the left eye, you use the right hand, and *vice versa*. The knife is to be introduced on the outer side, a little before the edge of the iris, then carried directly across to the opposite side, where it is to be brought out, and then carried down, making a semi-circular flap; the eyelids are to be let go, and the patient suffered to rest till the eye is steady. The hook is then to be introduced, and turned towards the capsule of the crystalline, which is to be scratched; next the instrument is turned down, and brought out, and with a very slight pressure the crystalline lens will escape. This operation requires a great deal of nicety; but, when properly performed, is more successful than couching. One great difficulty in performing it is, that of steadying the eye. A variety of specula have been formed for keeping the eye fixed; but none, I think, can be trusted to; they all make pressure on the globe, which endangers the escape of the vitreous humour. We are therefore under the necessity of trusting to the resolution of the patient: if this be not sufficient, you must wait till you have a convenient opportunity of introducing the instrument. When introduced, the eye may have some motion, when you must desist till the patient brings the eye outwards, which he will do at last for his own ease. The incision should be made with the greatest steadiness, or you will not have a good cicatrix, or the iris may be injured, or by making too

much pressure on the globe with the instrument, part of the vitreous humour may escape. When the cataract is fluid, perhaps part may come away, and part remain behind; more pressure is to be used for removing the remainder. If it cannot be done in that way, a scoop should be introduced to produce the effect.

After the operation, every thing should be removed that would tend to bring on inflammation. The patient should be placed on his back, with his head elevated, and topical applications should be used.

It is common for authors to speak of the ripeness of cataracts, by which they mean that cataracts are of a different consistence, and that it is or is not arrived at a proper consistence for extraction. If there should be any considerable degree of adhesion in the iris, we should not perform the operation. We may ascertain this by placing the patient before a window, first shutting, then suddenly opening the eyelids;—if there is any motion, there can be no considerable adhesion. Nor should the operation be performed if there is any considerable opacity of the cornea. When the iris adheres, the pupil does not contract equally, but irregularly. Some surgeons say this can make no objection, but I cannot agree with them. If it adheres in a slight degree only, the operation may be attempted; but if the adhesion is general, it cannot be done without tearing the iris; consequently the red blood will be thrown on the aqueous humour, and render it turbid; hence the patient will become blind, and perhaps be troubled with violent headaches during life. The laceration of the iris would bring on inflammation, and perhaps suppuration. Likewise the operation should not be performed where the patient has no sense of light—cannot distinguish night from day; which shews that the optic nerve is the immediate organ affected; for when blindness arises from an opacity in the crystalline humour, the patient can distinguish night and day, and knows when he comes near any luminous body. The operation should not be recommended when only one eye is affected, as the inconvenience is very trifling, and persons have been known to labour under cataract without being sensible of it, and we cannot be sure of inflammation not arising in the other eye, as there is a communication of the optic nerves within the cranium, which may affect the sound eye. Previous to the operation, and to avoid any bad consequences, the patient should be prepared for a week on low diet; and if plethoric, venesection, and a few doses of physic, should be premised. Some time after the cataract has been removed, the opacity still remains, which

depends on the capsule being thickened. The capsule of the crystalline may be absorbed, which I believe generally does take place after the crystalline is removed*, it being appropriated to the containing it; therefore, like many other unnecessary parts, it is removed, as the alveolar processes, thymus gland, &c. Since having performed this operation, I have met with it in several instances. In some, the opacity has come on after the operation; this, it is very easy to conceive, results from the laceration which takes place of the capsule: it becomes inflamed, and produces opacity, but which at length disappears. I have met with one or two cases where the opacity came on after the operation. In one, it has remained ever since the operation, as far as I know, the person having since gone to the West Indies. After the operation, every attention should be paid to the abatement of the inflammation by proper evacuations, such as leeches to the temples or towards the inner canthus, and letting blood freely when the eye becomes painful. Every now and then the pain is but inconsiderable, when aq. veget. min. will be sufficient to abate the inflammation. In about three weeks they generally begin to have a little use in the eye. Sometimes we find that the pupil is altered in its figure after the operation is performed. When you have punctured the capsule, the pupil generally contracts: in getting out the cataract, some laceration is produced, and an oval-formed pupil is the consequence. However, where I have met with this no inconvenience has followed. I have seen two instances where the pupil was oval before the operation. One was in a young lady about 18, who had cataracts from about ten years of age. It was remarkable that her father had cataracts when a young man, in whom was the same formed pupil; and she had a sister of about the same age, who became blind. In one of her eyes couching had been successfully performed twice; the other eye was pronounced unfit for the operation. I was consulted, and on examining the eye with a good deal of care, could find no other defect than the cataract. I performed the operation, and with success. In this she told me that the attempts at depression produced much more pain than the extraction. This cataract seemed to me broken in pieces. Sometimes after the operation has been performed the pupil becomes contracted, of which I have seen one instance in a patient where I performed on both eyes, so that scarcely any

aperture was left, and there was opacity in one eye. What could be the reason of this*, I cannot say. In the other eye she remains perfectly well.

*Cutting or perforating the iris.**—Now and then the pupil becomes contracted, and its cavity obliterated—the patient, of course, blind. Mr. Cheselden was the first who described an operation for the relief of this complaint, performed with a knife, which he directs to be introduced into the cornea, the point directed to the middle of the iris, which is to be opened for a considerable extent, to give room for the rays of light to pass to the retina. He performed this operation twice, with success as he thought, but it proved otherwise. Mr. Sharpe mentions this operation having been once performed with tolerable success. Probably there is some diseased disposition going on, and little to be expected from the operation; but the patient being quite blind, and it giving little pain, it may be right to try it.

Removal of the eye.—Sometimes the eye is in so cancerous a state as to require entire removal; occasionally it is altered entirely; there seems to be opacity, apparently as if the vitreous humour was changed†. This is a disease which is not very unfrequent, and the brain itself seems to partake of the diseased affection. In cases of this kind the operation is attended with extreme pain. If the eyelids are in a sound state, it is better to preserve them. On account of the situation of the eye they should be separated at the angles; this gives sufficient room to carry the knife round the globe, dissecting it entirely from the orbit, which is attended with great pain, on account of the nerves situated among the muscles, besides which, cutting through the optic nerve gives severe pain. There is generally a profuse hæmorrhage. This operation has in some instances been successful; while in others, where the eye has been removed, and the

* This contraction of the pupil is ascribed to iritis, and an adventitious membrane is sometimes the consequence.—C.

† By this is meant the formation of an artificial pupil—an operation which was in its infancy at the time these lectures were delivered. In reference to this subject, Mr. Lawrence (in his work on the Diseases of the Eye) makes the following observation:—"Although the first attempts of this kind were made in the earlier part of the last century, the operation was not much practised towards its very close; since which period so much attention has been paid to it, so many persons have investigated and attempted to improve it, that the methods of proceeding, and the instrumental apparatus, are perhaps more diversified than in any other surgical operation."—C.

‡ Probably fungus hæmatodes is here alluded to, which, in the first stage of the affection, exhibits a deep-seated discoloration at the posterior part of the eye.—C.

* Mr. Lawrence, and other eminent surgeons, differ in opinion with Mr. Cline on this point, considering that the capsule is not absorbed.—C.

part put on a healthy disposition for some time, the wounds have changed, and put on an unhealthy cancerous appearance. This is a simple operation: all that is necessary is, merely carrying the knife round the eye, dissecting it out, with the cellular membrane adhering.

CLINICAL LECTURE
ON
DISEASES OF THE HIP-JOINT,

Delivered at St. George's Hospital,

BY SIR BENJAMIN C. BRODIE, BART.

LECTURE II.

THERE are two important circumstances in the history of the scrofulous disease of the hip, which I neglected to notice. One is, the shrunk flattened appearance of the nates. This appearance is not, in fact, an absolute diagnostic mark of disease in the hip-joint, though it does usually accompany it. It arises simply from the wasting of the muscles. If you tie up one arm the muscles will waste; if it be painful to use the knee, and it be not employed, the muscles of the thigh waste; if it be painful to use the ankle, the muscles of the leg waste; if it be painful to use the hip, the muscles of the hip waste; and the largest muscles of the hip are those situated posteriorly, the *glutæi*. These are the muscles of which the wasting is most perceptible, and thus you will understand the reason of the altered form of the nates. This flattened appearance of the nates may occur, not only in cases of diseased hip, but wherever there is any thing which prevents the hip joint from being moved; as, for instance, in that paralytic affection to which young children are liable. I have known a painful tumor in the groin, and disease in the thigh-bone, produce the same effect, although the hip-joint was perfectly sound.

In some cases there is an alteration in the appearance of the nates from another cause. If the acetabulum be filled up with lymph, the head of the thigh-bone must be pushed more or less out of the socket, and this being the case, the great trochanter must project farther on the side of the disease than on the other, so that the nates become actually widened. Then, again, if the head of the thigh-bone be quite pushed out of the socket, and lodged on the dorsum of the ilium, the appearance of the nates must be different to what is natural. The great trochanter is prominent behind, and the head of the thigh-bone may be felt or even seen through the wasted *glutæi* muscles lying on the dorsum of the ilium.

Another of the symptoms of this disease is an apparent elongation of the limb. In the advanced stage of the disease the limb is always shortened; and I have explained to you how that occurs. But in the early stage of the disease there is sometimes the appearance of elongation, and there may, indeed, be some absolute elongation, though it cannot be much; for if you look at the skeleton you will see that the acetabulum looks a little downward, but more outward. If the acetabulum be filled with lymph or matter, and the head of the thigh-bone be pushed out, this must be in the direction outwards rather than downwards. The absolute elongation of the limb can never amount to more than half an inch, yet it appears sometimes to be elongated to the extent of two inches. This arises from the distorted condition of the pelvis. It makes with the spine an obtuse angle on the side of the disease, and of course an acute angle on the other side. The tuberosity of the ischium is lower on that side than on the other. Observe the position in which the patient places himself when he stands. In order to save the diseased hip from supporting the weight of the body, as much as possible, he throws his principal weight on the foot of the sound limb, while he advances the other foot merely to steady himself. But this cannot be accomplished without the tuberosity of the ischium being a little depressed. The apparent elongation of the limb often vanishes when the patient has been some time in bed. Occasionally I have seen an apparent shortening of the limb, without a real shortening, produced by the pelvis being twisted in an opposite direction.

In order to know whether a limb is shortened or elongated, it is not sufficient to look at a patient as he lies in bed. You must lay him flat on his back, and take care to place the two limbs parallel to each other, so that a line which passes from the patient's chin straight over the navel and the symphysis pubis, should go exactly between the knees. When you have placed him in this position, the two thighs making exactly the same angle with the pelvis, you measure with a tape from the anterior superior spinous process of the ilium to the patella. It is only by this method that you can acquire a knowledge of the comparative length of the two limbs. If you trust to your eye, and not to the measurement with a tape, you will be continually deceived.

Primary Ulceration of the Cartilages.

I give this name especially to a class of cases in which ulceration of the cartilages takes place in a different way from either of those already described. The disease begins

in the harder textures; but it is not preceded by that soft or scrofulous condition of the bones which I then described. The first thing that you observe, if you happen to have the opportunity (as I have had many times) of examining the body after death, where the patient has died in the early stage of the disease, is a destruction of the cartilage by ulceration. Here is a very fine specimen [presenting it] of what I now mention. Looking at it, you will see that the synovial membrane and the ligaments are in a natural condition; that the cartilage is absorbed from a considerable portion of the acetabulum in two spots; and that the cartilage covering the head of the bone has not its natural structure, but is converted into a sort of fibrous substance. The soft parts are in a natural condition, and also the bones. The latter are perfectly hard, having none of the scrofulous alteration which I mentioned in the last lecture. There are other specimens on the table, shewing similar appearances.

Now this ulceration of the cartilage I believe to begin in different ways: sometimes in the cartilage itself, which becomes converted into a fibrous substance first, and that fibrous substance becoming ulcerated afterwards. Here is a specimen, in which you perceive the disease in these two different stages; for while the cartilage of the head of the femur is converted into a fibrous substance, that of the acetabulum is completely absorbed. Here is another preparation [shewing it] where the cartilage is converted into a fibrous substance, actual ulceration not having as yet taken place. There was a body in the dissecting-room, in which many joints were affected in this manner. In some the cartilage was converted into a fibrous substance; in others it was ulcerated away, and the carious surface of the bone exposed. In some joints the disease had gone to a greater extent than in others. Here is a preparation of two patellæ, where you see ulceration of the cartilage going on. In one the cartilage is merely converted into a fibrous substance; in the other it is completely destroyed by ulceration.

Then I have reason to believe that in other cases the disease originates not so much in the cartilage itself as on the surface of the bone to which it is connected, and that it corresponds to what happens in cases of periosteal nodes. In syphilitic, mercurial, and some other nodes, you know that the first thing that calls your attention is often the thickening of the periosteum. But the fact is, that there is a previous alteration in the condition of the bone, which becomes inflamed and ulcerated under the periosteum, and then the thick-

ening of the periosteum is consequent upon the disease on the surface of the bone. The bone is more vascular and of a darker colour than healthy bone, and you may peel the cartilage off its surface. In this specimen you perceive that the surface of the bone is of a dark colour, and that the ulceration began on the surface of the cartilage which is towards the bone.

In practice I do not pretend to distinguish these two orders of cases from one another, any more than I can in practice distinguish those cases in which nodes are the consequence of disease beginning in the periosteum, and other nodes which are the consequence of disease commencing in the bones.

Ulceration of the cartilage, beginning with the conversion of it in the first instance into fibrous structure, is one of the diseases of joints to which persons are liable in old age. I have seen a person, 60 years of age, have disease and abscess in the hip-joint in consequence of this kind of ulceration in the cartilage. Ulceration of the cartilage sometimes takes place as a consequence of rheumatic affection. A patient, for example, came into the hospital who had been exposed to damp and cold. He had pains in the whole of the lower limbs, and in one shoulder. The man died from some other complaint—I believe from an attack of fever—and I examined the body. There was no affection of the soft parts, no disease in the bones any where, but in the right hip the cartilages were ulcerated to a great extent. There was pain in the other parts of the limb, but no ulceration of the cartilages any where else. There was pain in the opposite shoulder, but there were no morbid appearances in it when it was examined. I have seen several other cases where ulceration of the cartilage has been preceded by pain similar to that from rheumatism, but without any affection of the soft parts.

Ulceration of the cartilage sometimes takes place in a very remarkable manner, as a consequence of inflammation and abscess in the neighbouring parts. Of this I have met with many examples. Here is a case [presenting a specimen] in which the cartilages of the knee-joint are extensively ulcerated, but there is no disease in the softer textures—no matter in the joint. It was taken from a boy who had had compound fracture of the femur, and an enormous abscess in the thigh, contiguous to the knee-joint, had preceded death. I have seen several other cases where a large abscess in the neighbourhood of a joint has been followed by ulceration of the cartilages to a great extent. Mr. Mayo has published some cases of the same description.

In those cases in which the cartilages are ulcerated independently of the serofulous disease of the bones, the progress of the complaint after the ulceration has taken place must be very similar to the progress of it in those other cases which I described in the concluding part of the last lecture. Pus is thrown out into the joint, and then the soft parts are affected, or the acetabulum being filled with lymph, the head of the thigh-bone is pushed more or less out of the socket: the ulceration of the cartilage extends, the bones become destroyed, the head of the thigh-bone is diminished in size, the margin of the acetabulum is more or less destroyed, the neck of the thigh-bone is drawn up and lodged on the dorsum of the ilium; and in other cases the head of the femur is pushed out of the socket, and there is dislocation. But I need not trouble you with a complete history of the symptoms, which I described in the last lecture. You have, in fact, almost all the symptoms which I mentioned as occurring in cases of serofulous disease of the bone.

But how are you to distinguish these cases in practice? You cannot distinguish them in all instances, but you may do so in most cases so as to make a diagnosis which will be very useful in practice.

In the first place you will judge something by the aspect of the patient's countenance. If he is not that kind of person whom you would judge to be predisposed to what is called serofula, it would be a reason for suspecting that it is not a case of strumous affection of the bone. Such affection of the bone almost invariably occurs in early life, and there may be ulceration of the cartilages, independent of serofulous disease of the bone, in early life also. But the latter may occur in advanced life as well; and if the patient be above 25 years of age, it is more likely that he will have simple ulceration of the cartilage, than the true serofulous disease. Another important diagnostic mark is this:—A much greater amount of pain attends the disease in its early stage, in cases of simple ulceration of the cartilage, than where the ulceration is combined with serofulous disease of the bone. One most remarkable circumstance connected with serofulous disease of the bone is, that there is so little pain in the first instance, the patient going on for weeks, and even months, limping, and yet the disease being scarcely noticed. But in simple ulceration there is generally severe pain at an early period. In serofulous disease of the bone you have very little pain in general, till the cartilages are extensively ulcerated, and matter begins to form, but in the other cases there

is a great deal of pain long before that period has arrived.

I have given you my notions of ulceration of the cartilages, but I should tell you that other pathologists have entertained different views respecting the functions of the cartilage, and its capability of being ulcerated. Among these pathologists I may mention especially Cruveilhier in Paris, and my friend Mr. Key, in this country; both of whom seem to regard the cartilages as being not vascular, and as incapable of ulceration, from the action of vessels belonging to itself. Mr. Key has indeed published a paper to shew that ulceration of the cartilage is the consequence in general of disease of the synovial membrane. He describes vascular processes of the synovial membrane as projecting into the joint, filling it up, and then, as it were, eating away the cartilage.

Now I do believe that if these gentlemen had taken as much pains as I have done to examine the bodies of patients who have died in the *early* stage of these diseases, they would have come to a different conclusion. They seem to have examined the bodies of persons when the disease was in a late stage, and when the morbid appearances were deceptive. The first question is, are the cartilages vascular or are they not? The cartilages of children are undoubtedly vascular—nobody can hesitate to admit that—till the period of growth is over. Growth could not take place otherwise. If you cut the articular cartilage of a growing child you see the vessels, or rather the sinuses, in which the blood flows very distinctly. The cartilages of children resemble the cartilages of adults in all essential circumstances. Some changes take place, as I shall mention presently, but still in all essential circumstances they resemble each other. Merely looking at the structure, you would say that if the cartilages of children are vascular, those of adults are vascular also. You see in this preparation, and in others taken from adult subjects, the alteration of cartilage into a fibrous structure; and how could such a morbid alteration of structure take place, if the part were not organized?

The epidermis, or cuticle, is not organized. You may have bad cuticle secreted; but being once secreted, it does not become altered in quality. The nails and the hair are not organized; you may have bad hair and bad nails secreted, but these being once formed, they do not alter. But this preparation [exhibiting it] and a number of others, shew that the cartilage does alter. It seems to me that this single specimen which I now hold in my hand is quite suf-

ficient to prove the organization of the cartilage. Look at the two patellæ in this preparation; the cartilage in one of them is clearly undergoing a change of structure, while in the other it is entirely destroyed by ulceration. How can this be accounted for, except upon the supposition that the cartilage is organized? Then observe what happens to cartilage in its healthy state; how it is exposed to friction, and if there were not a power in cartilage of regeneration, how could it bear the quantity of friction to which it is exposed during life? Take the example of a wild animal, with its limbs in constant motion, the cartilage constantly exposed to friction, except during the hours of sleep, yet all this produces no change in it. But if there were anything else there, an elastic substance, such as caoutchouc, or the hardest metal, as gold or platina, would it not be worn away? The living body is subject to the same mechanical laws as dead matter. The fingers of a mechanic would be worn out if their organization did not enable them to repair the loss occasioned by the destructive power of friction. Are not the articular cartilages placed under the same circumstances? How can you explain their durability, except by supposing them to be endowed with vital powers and organization?

You cannot see blood-vessels in the healthy cartilage of an adult; but does that prove that vessels in it do not exist? You cannot see vessels in the transparent cornea, but who doubts its vascularity?

Besides what I have already mentioned, it would be easy to indicate many other changes in cartilage which must be referred to organization and vascularity. The cartilage of a young man and the cartilage of an old one differs in many respects. There is difference of colour, of thickness, and consistence, sufficiently marked, which cannot be the effect of friction, which can only be attributed to a change taking place in the cartilage itself.

I have already adverted to the analogy between the cornea of the eye and the articular cartilages. But it may be said that in the cornea you have the proof of its being endowed with vessels, in its liability to inflammation; and it is quite true that in long-continued ophthalmia you may see the blood-vessels running into the substance of the cornea, injected with blood. But you may see just the same thing in the cartilages of the joints. I have observed it distinctly in many instances. Two or three instances of this are recorded in my work on Diseases of the Joints. A man, for example, had that scrofulous disease of the ankle which I described in my last lecture. The cartilage in some parts was ulcerated,

in others it was beginning to ulcerate. Where it was beginning to ulcerate there were red spots, into which I could distinctly trace blood-vessels shooting from the neighbouring bone, exactly corresponding to the blood-vessels which shoot into the transparent cornea in cases of ophthalmia. Mr. Mayo has described a case of the same kind, and I believe that in the Museum of King's College the specimen which he met with is preserved, and that the vessels running into the cartilage are seen injected with size and vermilion. Now taking all these things into consideration, I really know not how we can refuse our assent to these propositions; first that cartilage is organized, and secondly that cartilage, like other parts which are organized and possessed of vital properties, is capable of ulceration.

To illustrate the subject still further:—In the subject from which this drawing was taken, there was an extensive absorption of the cartilages of some of the tarsal bones, the os calcis, the os naviculare, and astragalus. Now observe how the absorption has taken place. In some parts the cartilage has disappeared altogether, and the bony surface is exposed. In other parts the cartilage is partially absorbed; it is rendered thin and semitransparent, so that you can see the brown colour of the bone through it; and the absorption has taken place on that surface of the cartilage which is towards the articular cavity, while the layer towards the bone remains entire, and retains its natural adhesion to it: a fact quite incompatible with the notion of its being absorbed by the vessels of the bone to which it adheres. There was no disease of the soft parts.

The preparation which I now shew you is of great interest; and in order that you should understand its relation to the present inquiry, I must briefly explain the patient's case.

There was a compound fracture of the thigh, and a portion of the femur was sawn off, for not till then could the fracture be reduced. An immense abscess formed in the thigh, near the knee-joint, but not communicating with it. The boy sunk and died, and on examining the body we found the large collection of matter which I mentioned in the thigh. The knee-joint externally presented no indication of disease; there was nothing the matter with the synovial membrane or the ligaments, no effusion of pus, or serum, or lymph, in the joint. All that we could discover was the disappearance of the cartilage. Now observe how it has disappeared. In the centre the cartilage is altogether absorbed, and the bone exposed. Then, in some parts, the

cartilage is partially absorbed; the surface of it towards the cavity of the joint having been taken away, while that which is next to the bone remains entire, and has its natural adhesion to it. You will see the cartilage in some parts putting on a peculiar grooved appearance, as if you had dug out a piece of it with a chisel. How could the cartilage be absorbed in this case, except from the action of its own vessels?

Mr. Key, in his interesting paper on Ulceration of the Cartilage, has given a drawing of the knee-joint, where the cartilage was affected in this manner—that is, partially absorbed on the surface towards the articular cavity; and this was in a case where the original disease had been inflammation of the synovial membrane. Large processes of inflamed synovial membrane are seen hanging pendulous into the joint, and he supposes that these pendulous processes of the synovial membrane came in contact with the different parts of the cartilage, and were the agents through which the absorption of the latter had taken place.

Without entering into the question as to how far this explanation is correct, as applied to this particular case, I may observe that it certainly is not applicable to the cases of which I have just given you the history, any more than it is to the cases of ulceration of the cartilage published by Mr. Mayo in the *Medico-Chirurgical Transactions*; in none of which these pendulous excrescences of the synovial membrane existed.

At the conclusion of this investigation, you will ask “what becomes of a joint of which the cartilage has been destroyed by ulceration?” If it be extensively destroyed without suppuration, the case may be compared to one of simple fracture; and if there be suppuration, it may be compared to one of compound fracture: and in either instance the ulcerated surfaces of the bone come together and ultimately become united. Bony ankylosis, however, takes place very slowly in the serofulous disease which I described in the last lecture; the bond of union being for a very long time nothing but a soft ligamentous substance. But in other cases, where the cartilage is ulcerated without serofulous disease of the bone, bony ankylosis takes place, I believe, readily enough. There may, however, be absorption of cartilage to a considerable extent, without it being followed by bony ankylosis. I shewed you, in the last lecture, a drawing where the cartilage had been ulcerated in several parts of the patella and condyles of the femur, in consequence of inflammation of the synovial membrane. The patient died a year afterwards, from dis-

ease of the chest; and on examining the body after death, I found that where the cartilage had been absorbed, it was replaced by a sort of ligamentous membrane. You will see the same thing in this preparation, where the cartilages of the hip have been partially absorbed, and replaced by a dense membrane. I cannot say whether this substance ever is or is not converted into true cartilage; perhaps it may be; but you know how difficult it must be to acquire any thing like satisfactory evidence on this point.

Treatment of Diseases of the Hip.

If you could always be exactly certain as to the nature of the disease in the hip-joint, of course you would be able to apply your remedies more precisely than you can with that sort of doubtful diagnosis which we are compelled to make in some cases. The diagnosis of diseases of the hip is more difficult than the diagnosis of the same diseases in other joints, simply for this reason, that the hip is not a superficial joint, but is covered by a great mass of muscle, and you cannot examine it with the hand as you can the knee, the elbow, or the wrist. We are necessarily compelled to depend more upon the history which the patient gives of the disease than when the other joints are affected. This history, going back as it often does to a long period, and in a great number of instances having to be drawn from very young persons, is often not much to be depended upon. There are, however, many cases of disease of the hip in which we are able to say at once what kind of disease exists in it; there are others where we must give a more doubtful opinion; but even here a careful investigation will generally enable us to make such a diagnosis as will be sufficient to lay a tolerable foundation for our practice.

There is one remedy which is applicable to all cases of disease of the hip, and this happens in all of them to be the most important part of the treatment, at least of the local treatment; and of this I shall speak first.

If your leg were inflamed, and you were to rub it a dozen times every day, would you not make the inflammation worse? If your leg were ulcerated, and you were to rub it in the same manner, would you not prevent the ulcer from healing? nay, rather, would you not make the ulcer spread? If the hip-joint, then, be inflamed, and you move it several times a day, will not the inflammation be kept up? If the cartilages or bones, or both, are ulcerated, and the joint be moved, and the ulcerated surfaces are rubbed against each other, is it not to be expected that the disease will be aggravated? Have we not a right, under all circumstances, to

expect that motion or exercise of the hip-joint will tend to aggravate the disease, whatever it may be; and that the keeping of the joint in a state of perfect repose will be a most important part of the treatment to be employed. In all cases of affection of the hip-joint, without inquiring into the nature of the disease, the first thing that you have to do is to keep the joint in a state of perfect repose. This may be accomplished in different ways. In one of the cases now in the hospital a quantity of bandage was rolled upon the pelvis and the upper part of the thigh; then stripes of adhesive plaster were put over the bandage; then other bandages were applied, and other stripes of plaster; and so on till a great mass of bandage and plaster, all sticking together, was fastened round the pelvis and round the upper part of the thigh. This has fixed the boy's hip-joint very firmly, and is very nearly the method which Mr. Scott, of Bromley, employs for all diseases of the joints. He, indeed, uses mercurial ointment spread on lint under the plasters; but this, I apprehend, to be perfectly unnecessary. The good which he attributes in diseased hips to the ointment, I attribute altogether to the support afforded by the plaster and bandage, forming a kind of splint, and limiting the motion of the joint. This method, in the case up stairs, and in a number of others, is productive of very good results. But a still better method than this, in the majority of cases, is that of applying a splint adapted to the hip-joint, thigh, and pelvis, such as are used for the knee and elbow, made of a very thick, hard, firm, strong leather, prepared without oil or other grease. This leather is prepared for the purpose, of cow's hide; and the consequence is, that on putting it into water a little below boiling heat, it becomes as soft as wet brown paper, and you may cut it out to any shape you please, and mould it to the hip, securing it afterwards by a bandage, and leaving it to dry on. This splint cannot fail to fit the joint, and must therefore be easy to be worn. Altogether it answers the purpose very well when the thigh is not much bent on the pelvis. Where, however, this is the case, it is very difficult to adjust the splint, and the plasters and bandages which I mentioned just now are preferable. There is still another method of fixing and supporting a diseased hip, which you will see carried into effect in one of the patients up stairs. The lad is placed on Mr. Earle's fracture or invalid bedstead. He lies there on his back; the shoulders are raised by one inclined plane, the thighs are raised by another, and the legs are supported by a third; so that he lies on

three inclined planes, and cannot slip upwards or downwards. The thigh is kept at that angle which is most convenient to the patient, and the two limbs are placed parallel to each other. Lying in this manner, the patient, you perceive, has very little motion; he can scarcely manage to turn, and has no inducement to attempt it. In this bedstead there is a sort of trap-door beneath, filled up with a cushion, which may be taken out when necessary, and which answers the purpose of a bed-pan, so that the patient has his evacuations without being in the smallest degree disturbed. This method is especially applicable to those who have passed the age of childhood, and in whom the disease is still in its most early stage.

It is of some moment that you should, before the disease is very far advanced, get the limb into a good position. A child especially has always a tendency to throw one knee over the other, and to lie on one side. The consequence is, that the thigh-bone gets twisted into an awkward posture, the pelvis and the spine are also twisted, and the whole figure is in a state of distortion. It matters not how trifling the disease may be, your first duty to your patient is to make him lie down at once. Take care to place him with his shoulders a little elevated, and his limbs parallel to each other, and thus you will prevent that ugly distortion of the whole body which always takes place where these precautions are neglected.

NATURE AND TREATMENT OF DELIRIUM.

BY M. B. GALLWAY, ESQ.

Assistant-Surgeon Royal Artillery, Woolwich.

[Concluded from p. 49.]

NOTWITHSTANDING all the evidence I have adduced to disprove the existence of a distinct and primary action within the head itself, as the exciting cause of the delirium in the form of disease under our notice, I am obliged to admit the very remarkable and embarrassing resemblance that exists between many of the symptoms which attend the inflammatory, and opposite, or asthenic, condition of the brain.

"Some of the more obvious and striking effects of loss of blood," says Dr. Marshall Hall, in his treatise on the Morbid Effects of Loss of Blood, "or those of reaction, are such as to suggest the idea of increased action in

some system, and of increased action in some of its organs, and to lead to an erroneous and dangerous employment or repetition of the lancet, when a directly opposite mode of treatment is required; while the state of actual but protracted sinking frequently resembles a state of oppression of the brain, or of congestion of the lungs, so accurately, as to prompt the unwary practitioner to a still more suddenly fatal use of the lancet."

"The result of this treatment," adds the same author, "is in itself again apt further to mislead us; for all the previous symptoms are promptly and completely relieved; and this relief, in its turn, again suggests the renewed use of the lancet."

In excessive arterial action within the head, we find, as prominent symptoms of that condition, throbbing of the carotid and temporal arteries, great intolerance of light, as well as of noise and disturbance of every kind; continued watchfulness and restlessness; rapid and suspirious breathing; and the pulse, though generally round and tense, in some urgent cases is soft, irregular, or intermitting.

Let us now turn to the symptoms of an opposite condition of the brain—exhaustion from loss of blood; and I cannot do better, I think, than quote from one of the many such cases detailed by Dr. Marshall Hall, in his treatise on Blood-letting:—

Mrs. —, having been frequently and largely depleted for an inflammation of the os uteri, consequent on parturition, was suddenly affected "with extreme pain of the head, violent throbbing of the temples, slight delirium and sickness, intolerance of light and sound, feverishness, and a frequent strong pulse." This patient craved for brandy, and, being allowed it, was obviously relieved, and ultimately rescued from her dangerous condition, by the further use of cordials, a mild diet, quietude, &c.

There are many such cases to be found in the work I have alluded to, but for brevity's sake I have deemed it expedient to extract one that did not involve a very long history, though very few offer more striking confirmation of the phenomena it is meant to instance.

As Dr. Marshall Hall describes them, such cases are attended with "beating

of the temples, and a throbbing pain of the head; morbid augmentation of the energies and sensibilities of the brain; intolerance of light, and still more frequently of noise; sometimes slight, occasionally even continued delirium. The action of the heart and arteries is morbidly increased, and there are great palpitation and visible throbbings of the carotids; the patient is often greatly alarmed, and impressed with the feeling of approaching dissolution; the pulse varies from 100 to 120 or 130, and is attended with a forcible jerk or bounding of the artery. The respiration frequent and hurried; the skin sometimes hot; and there are frequently general hurry and restlessness."

Dr. Marshall Hall in another place, makes these few but impressive remarks, all bearing on the point at issue:—"The symptoms of exhaustion with reaction have, I am persuaded, frequently been mistaken for those of inflammation or other disease of the head or of the heart. Under this impression recourse has frequently been had to the further detraction of blood by the lancet; and the effect of this practice is such as greatly to impose upon the inexperienced, for all the symptoms are perhaps greatly relieved."

The very frequent and often jerking pulse attendant upon diseases of exhaustion, is well accounted for in the following words of Dr. Philip Wilson, taken from his essay on the Nature of Fever:—

"It is not difficult to perceive the final cause of the beats of the heart generally becoming more frequent when they are enfeebled; for the feeble systole not propelling the same quantity of blood, or not propelling it with the same velocity, a more frequent systole becomes necessary in order to support a due vigour of circulation."

The very interesting and extensive nature of this latter consideration, viz. the close resemblance between the symptoms of plethora and anæmia of the brain, may appear to have drawn me into too long a digression from my more immediate subject—delirium; but I think they will not be deemed misplaced, when it is remembered that a principal feature in this paper, from the beginning, has been to account for the occurrence of delirium, in very many cases, on the presence of a condition

of the brain opposed to that of excitement.

Having disposed of the form of delirium peculiar to adynamic or typhoid affections, I am anxious to say a word on another remarkable and not very frequent variety of it, inasmuch as it has lately occurred to me to witness a striking instance of the same.

I was sent for by Lord C., to attend a groom, who was represented to me as being in a state of madness consequent upon a fall on the head. I found him in a state of furious delirium, requiring the assistance of four or five people to keep him down in his bed. From the violence of his struggles it was with much difficulty that I was able to examine his pulse and general condition. I found, however, the former scarcely accelerated, and in character soft and compressible. His features, too, did not indicate the presence of determination to the head. I learnt, on inquiry, that this man had met with a fall on the head a week prior to the invasion of his present symptoms, but that no ill consequence had ensued, and he had been able to pursue his usual avocations up to the day on which I saw him. That, on a sudden, without forewarning, he had been seized in the manner I found him in, and had been perfectly rational a few minutes prior to the attack of delirium. I made a careful examination of the head, but could detect no inequality in the surface of the cranium; nor, indeed, was it to be anticipated, from the previous absence of cerebral symptoms.

I have seldom felt more at a loss to act with decision than in the present instance—whether, in fact, the condition of this man required a copious blood-letting, or a tea-spoonful of laudanum? The circumstance of the long interval that often elapses between an injury inflicted on the head and the invasion of phrenitis, seemed to favour the adoption of the former; whilst the suddenness of the attack, and the absence of the usual symptoms denoting an inflammatory state of the brain, went far to incline my belief in the necessity of the latter.

A strait-waistcoat, however, being necessary, in order that his head might be shorn and his own personal safety provided for, I directed that this measure might be at once carried into effect,

when I would return and examine the case more attentively.

Scarcely more than half an hour had elapsed, when, on my return to the patient, I was informed he had expired a few minutes before. A practitioner, whom I met in attendance on this case, had deemed it expedient, shortly after my departure, to bleed him; and I understood that he bore the depletion well; but he sank shortly afterwards, exhausted by the continued and violent struggles he had made from the commencement of the attack.

What was the condition of the brain giving rise to the delirium in the preceding case? It may not be easy to answer this question satisfactorily; but I very much incline to the opinion, that it was not one of inflammation! And I think, moreover, that I should not hesitate, were I to meet again with a similar case, to exhibit a large dose of opium for its relief.

What surprised me not a little here was, the rapid exhaustion which ensued upon the previous state of almost athletic violence. Half an hour before death, he had required the assistance of his wife and two men to confine him in bed. In cases of hydrophobia I had witnessed the gradual approach of exhaustion consequent on a long-continued state of nervous excitement, and believe death in such cases to be the immediate result of the collapse of the system engendered by a degree of excitement it is unable to support, decidedly as cause and effect. But under such circumstances the exhaustion has been slowly and gradually induced. Whereas, in the case of which I have given a brief outline, it set in without warning, on a state of violent excitement existing but a moment before.

Van Rotterdam mentions a somewhat similar case of furious delirium, suddenly setting in at a moment's notice, in which the patient opened a window and threw himself out on the roof of a house.

Again, Dr. Marshall Hall, in the work I have so often alluded to, relates a case of great interest, wherein a lady, having been bled repeatedly for abdominal tenderness consequent on parturition, and brought into a passive but debilitated state, was suddenly thrown into a state of wild incoherent delirium, through "some family occur-

rence of a trifling nature; and after a restless night, was found next day in the highest state of excitement, talking incessantly, screaming and struggling, with a wild expression of countenance, and a small rapid pulse." This patient's state was not ameliorated by leeches to the head, cold lotion, &c.; the delirium, on the contrary, continued "incessant, loud, and wild, without an instant's interruption for twelve hours." A full glass of wine repeated every hour, restored her, at the end of the fourth, to a state of perfect composure, and she thoroughly recovered.

There can be no doubt, I think, in this case, that loss of blood was the cause of the maniacal state she fell into. "I am persuaded," says Dr. Hall, "that loss of blood is by far the most frequent and influential source of delirium or mania occurring in the puerperal state."

I have long been convinced of this myself; though it has been my painful lot, in two cases of this nature, wherein I had no voice, to remain a passive spectator of the reapplication of the lancet. One of the unhappy patients died under the operation, because, peradventure (as Dr. Sangrado affirmed, on beholding his patient die under the repeated abstraction of blood), because "he had not been bled enough."

There is a form of delirium described by our English Hippocrates (Sydenham,) which seizes some people at the very point of convalescence, and wherein he warns us "not to apply here the *ordinary cure of delirium*; it, on the contrary, must be cured by quiet, by tonic remedies, and generous diet; since this kind of delirium seems to proceed, not from sanguineous congestion in the cerebral organ, but from exhaustion of the vital energy. It is on this account that it is not here necessary even to administer local bleeding; and if, as it frequently happens, such subjects be bled under pretence of removing the sensation of weight from the head, or the tedious drowsiness, the period of returning vigour is retarded, and sometimes an imbecility is induced for the remainder of life."

Dr. Burne, in his Treatise on the Adynamic Fever, alludes to the same circumstance, where he says, when the fever is on the decline, "there takes place watching, with a peculiar staring, rather brilliant, and observant eye, and

frequent lifting up the head, as it were to listen, and mild delirium; the stroke of the pulse is short, and leaves no impression on the finger, and the artery is very compressible. These signs must not be mistaken for irritation or sub-acute inflammation of the brain: they occur in patients who have lost much blood; they are the result of that loss, and depend immediately on a defective arterial impulse, and defective supply of blood to the brain."

I have hitherto been silent on that variety of delirium so frequently occurring as the offspring of intemperance; nor will the limits of my paper allow me to do more than briefly allude, on this occasion, to it, as involved under the subject I am treating of.

Delirium tremens, indeed, opens at once a field of too much extent, as well as one too imperfectly understood, to admit of being summarily disposed of in a few words. I shall, therefore, merely remark, *en passant*, what I believe is now very generally admitted, that the condition of the brain giving rise to it is much more one of exhaustion from previous over-excitement than of actual excitement *in ipso*. This symptom of trembling attendant upon delirium, was looked upon as of the worst augury, as early even as the time of Hippocrates; for we find that great man himself averring, that "if trembling accompanies delirium, it is constantly fatal." And at a later period, the learned Stoll declares that such an accompaniment is "always mortal." It is true that *we* do not go quite to this length in our present views of the danger attending a combination of these two symptoms; although such a condition must always be deemed at least unfavourable.

Whilst on the subject of delirium tremens, I may take the occasion to mention, that a plan of treatment was recently put in practice, at the Ordnance Hospital, at Woolwich, by the suggestion of my friend, Mr. Whitfield; the originality of which, I believe, he has every claim to. That gentleman prescribed, in a case of severe delirium tremens, the tartar emetic, in consequence of the success he had met with from its use in a tropical climate. He believed that he had there established its superiority over the opium and stimulant plan, in tranquillizing the nervous

system, and succeeded with this remedy when other means had failed. In the present instance he began with a grain every hour, which seemed at first to quiet the system. It was soon increased to two grains, and subsequently to three; but now its action on the skin and stomach, when pushed to this extent, obliged him to discontinue the remedy. Mr. Whitfield then substituted, for the emetic tartar, camphor and opium, under which treatment the symptoms were rapidly subdued. Still he declares that the failure of his remedy in this instance will by no means discourage him from having recourse to its use on future occasions: and though I am very far from being a convert to his views on the subject, I must admit that the safety of the remedy, as applied to the disease in question, has been fully established by him; as was also its tolerance in the dose of two grains every hour: a large amount, indeed, of the medicine, had the system even been fortified by inflammatory action!

Before I take leave altogether of my subject, I would beg leave to remark, in reference to the great question at issue—is the brain the seat of inflammatory action, or is it not, during the existence of certain questionable symptoms during life?—that how much soever it may continue to be matter of doubt if the patient lives, I agree entirely with Laennec, that it can no longer continue a mystery should the case afford a post-mortem inspection. I think him justified, I say, in his opinion, that as a general and constant rule, the deposition of a new product, such as pus or coagulated lymph, is the only genuine or incontestible proof of the previous existence of inflammation. The same opinion is entertained and strongly inculcated by Dr. Burne, in his *Treatise on the Adynamic Fever*; in which are contained some excellent practical remarks, under the head *Delirium*.

“Upon the whole,” says Dr. Hall, “it seems highly probable that a certain balance of the circulation of the brain is necessary for the healthy condition of the functions; that they are equally impeded by the interruption which takes place in apoplexy, and the diminished impulse which occurs in these opposite conditions. What, indeed, is syncope, but an abolition of sense and motion? It is preceded by

giddiness, tinnitus aurium, and impaired vision; and is accompanied by blindness, dilated pupil, perfect insensibility, and not unfrequently passes into convulsion. It differs, then, from apoplexy, chiefly or entirely in the state of the general circulation; the symptoms accompanying the two affections being remarkably similar, and the effect upon the sensorial functions almost entirely the same.”

“Some physiologists,” says Hunter, “will have it, that the stomach is a mill; others that it is a fermenting vat; others, again, that it is a stew-pan: but in my view of the matter, it is neither a mill, a fermenting-vat, nor a stew-pan—but a stomach, gentlemen; a stomach!”

Precisely so is it with the brain. It may be the seat of the soul, of the senses, or what not; but it is after all a brain, and nothing but a brain; and, as such, is subject to the same laws which regulate the other material organs of our system. It may be excited by causes which increase the circulation within it, or depressed by others which exhaust its energy; and though we are as yet but imperfectly acquainted with its physiology, and are unable to account for some anomalous symptoms it occasionally presents to our notice, we must ever bear in mind that its beautiful mechanism is compiled out of precisely the same elements as all the other parts of our body, and may naturally, therefore, be suspected of being subject to the same diseases; the variety in the symptoms of some of them depending, no doubt, on the peculiarity of its circulation and the delicacy of its own texture.

Let us not, also, in our views of some of its most complicated diseased conditions, be led on too far by established theories; which, though always excellent, as great land-marks to the physician, are occasionally found to be treacherous beacons when too closely followed. “Human experience,” says Dr. Johnson, “which is constantly contradicting theory, is the great test of truth.” And Celsus reminds us, that even medicine obeys no invariable laws: “*Nulla perpetua præcepta medicina recipit.*”

NEW METHOD OF TREATING BURNS.

To the Editor of the Medical Gazette.

SIR,

In the year 1831 you did me the favour to admit a paper of mine to a place in the *GAZETTE*, promulgating a new method of treating burns. I am now induced to request you will also insert the following paper on the same subject, when you can afford space. It details the circumstances which first gave rise to the idea of curing burns without the intervention of suppuration; and I sincerely hope its perusal will induce many of the profession to try the plan there suggested, which I feel confident will not disappoint their expectations. In principle it is analogous to M. Velpeau's, only it is more fully carried out, and, under favourable circumstances altogether prevents suppuration, while his plan only diminishes it.—I remain, sir,

Your obedient servant,

EDWARD GREENHOW, M.D.

North Shields, Sept. 1838.

The most various and opposite modes of practice have been adopted in the treatment of burns: while one party has advocated the use of cold and sedative applications, another has extolled the efficacy of stimulating ones; and although, doubtless, much depends upon the nature and extent of the injury, nevertheless there seems to be a want of some sound principle of practice, which, when once established, might be modified according to the exigencies of each individual case.

Professor Velpeau, in an excellent memoir, published in the "*Revue Médicale Française et Étrangère*," for June, 1835, takes a review of the effect of the different modes of treating burns, of which injury he recognizes four degrees: the first comprises simple rubefaction, the second vesication, the third the destruction of the rete mucosum and first layer of the true skin, and the fourth, where a part of the whole thickness of the skin is converted into an eschar.

The merits of various remedies for burns are examined in relation to these degrees; but it is unnecessary to notice these, with the exception of a new plan

adopted by M. Velpeau, which is equally applicable to each of the four degrees of burns; and this plan is to apply straps of diachylon plaister around the injured limb, precisely in the manner recommended by Baynton, many years ago, in the treatment of ulcers. This plan M. Velpeau has found eminently successful, the dressing only requiring to be renewed, if the suppuration is profuse, every second day; otherwise every third or fourth day is sufficient. No doubt this plan has the effect of materially diminishing suppuration, by making a gentle and equal pressure upon the injured parts, and also by excluding the atmospheric air. In these respects it bears a close relation to a plan which I have pursued most successfully for many years, a short notice of which appeared in the *LONDON MEDICAL GAZETTE*, in October 1831, which plan, in many instances, has the effect of healing burns by the first intention, without the intervention of suppuration, and where from circumstances it does not entirely accomplish this, it very considerably diminishes the suppurating surface, and in all cases prevents the cicatrizations forming bridges, which under other modes of treatment so often produce contractions of the limbs and disfigurement of the countenance. But before I proceed to detail this mode of treatment, it may not be uninteresting to state the circumstances which first suggested the idea of curing burns by the first intention.

It is somewhat more than twenty-five years since I was consulted for a boy, who had fallen with both his arms into a kettle of boiling pitch: the agony he suffered at first was extreme, but as the pitch became cool, so did the pain abate. Upon examination I found his hands thickly coated with pitch, which also had found its way up the jacket sleeves, and probably also through the texture of the cloth; at all events, the sleeves from the wrists almost to the shoulders were firmly glued to the arms in a solid compact mass: the pitch on the hands after much trouble was got off by the free use of *sp. terebinthinæ*, and they were dressed with *Ung. Resin. Flav. cum Ol. Terebinth.*; but with the arms I could do nothing. After vainly attempting to dissolve the hardened mass I abandoned it in despair, by no means easy as to the result of leaving it alone: however, he made little complaint of the

arms, and in the meantime the hands suppurated copiously, sloughs separated, granulations rose, and skin began to form in various points. It was now three weeks since the accident, and there had been no appearance of discharge from the arms, no offensive smell—nothing, in fact, to indicate that any process was going on: at the end of that period, however, I was delighted to find the sleeves of the jacket begin to loosen, and detach themselves from the arms, and in two or three days more I was enabled to rip them up and remove them altogether, when to my surprise I found the arms perfectly healed, and covered with a new skin, whereas the hands were not entirely healed until a month afterwards: on closely examining the jacket-sleeves there was found adhering to them a substance resembling thin leather, which I could not doubt was a slough, which had separated from the arms; and this had taken place, and the whole healing process had been accomplished, without the intervention of suppuration.

This case made a great impression upon my mind, and I endeavoured to devise plans for imitating the coating of pitch, which had so wonderfully healed the burn which it had itself occasioned. In talking the case over with a friend, in Newcastle, who was largely engaged in attendance upon collieries, in which cases of burns were of frequent occurrence, we agreed that on the first occasion that presented itself, instead of dressing, as we had been accustomed, with *Ung. Resin. Flav. cum Ol. Terebinth.* spread upon lint, to use the same ointment, melted over the fire, and applied with a brush or bunch of feathers, so as to form a complete coating over the burnt surface. It was not long before an opportunity presented itself of trying this plan upon an extensive scale, for not many days afterwards the friend above mentioned was summoned to a colliery where an explosion had taken place, and twenty-nine individuals, men and boys, were brought up, all of them more or less burnt, and many of them extensively and severely; all the brushes and feathers of the village were immediately called into requisition, and with the assistance of the relatives of the sufferers, in a very short space of time they were all thickly coated with the ointment, they uniformly expressed them-

selves as much relieved, and they experienced none of the rigors, so distressing after a burn, and the certain prelude to suppuration. The assistants were strictly enjoined to preserve the perfect integrity of the coating, by renewing* it as often as it became necessary, and the men themselves were cautioned to move as little as possible, that they might avoid rubbing off the coating. It is unnecessary to dwell long upon these cases. They all recovered; many of them without the slightest suppuration taking place, and others having it take place only in a very partial degree; and although the faces of some of them were severely burnt, no suppuration took place in any one of them; and it was only in places where friction could not altogether be avoided that suppuration took place at all, and on those parts where sloughs necessarily formed, in consequence of the depth of the injury, the sloughs peeled off like pieces of shrivelled leather, as the surface skinned beneath them.

The result of these cases was most satisfactory, establishing not only the possibility of healing burns without suppuration, but also that this was accomplished in a much shorter period than could have been effected by any other mode of treatment, and also that the constitutional irritation bore no comparison to what it would have done had there been a large suppurating surface: in point of fact, many of these men were burned so extensively, that had suppuration taken place, the probability is, that the system would have sustained a shock which would have proved fatal.

Since the period at which this occurred I have pursued the same plan in the treatment of burns, and every succeeding year has served but the more to convince me of the advantages it possesses; and the friend I before alluded to never employed any other mode of treatment up to the end of his life. This plan also, like M. Velpeau's, is applicable to any of the four degrees of burns; and where it is desirable to make the coating of a firmer consistence, it is easily accomplished by the addition of a little bees' wax or resin to the vessel in which the ointment is melted.

Within the last few weeks I have seen the case of a female who set fire to her cap, which, together with her neckerchief, were entirely consumed, leaving her face, neck, throat, and part of the

breast, very severely burnt. She was treated according to the above plan; and although, from the depth of the injury, several sloughs formed both upon the face, neck, and ears, yet not the slightest suppuration took place, and the whole surface healed without leaving a vestige to indicate that such an accident had ever occurred.

ANALYSES AND NOTICES OF BOOKS.

—
 “L'Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D'ALEMBERT.

—
The Spas of Germany. By A. B. GRAYVILLE, M.D. F.R.S. &c. Second Edition. London, 1838. 8vo. pp. 516, and lviii. With 39 Illustrations and Maps.

[Concluded from page 21.]

THE Wildbad water is very soft and pure, containing only one grain of solid matter in a pint, according to Stauden Mayer; and three and a half, according to the more recent analysis of Drs. Sigwort and Weiss. Of this, common salt forms one half, after which come the carbonate and sulphate of soda, and the sulphate of potash, carbonate of lime, and carbonate of magnesia. Some chemists have also found very slight traces of iron, together with indications of a little animal and bituminous matter.

Liebenzell, which is in the kingdom of Würtemberg, at no great distance from Wildbad, possesses two cold, or rather tepid springs, the one having a temperature of 77°, the other somewhat lower. In chemical composition it resembles the Wildbad water, but the quantity of solid matter is greater*.

These waters are heated, but that of the lower well is employed by many in its natural state.

“I have been assured that these baths have been found very useful in scrofulous diseases, and in consumption, accompanied with tubercles; in which latter condition of the lungs, it is said that the exhalation of the surrounding fir forests is also particularly serviceable. In hæmorrhages of all sorts, such as

spitting of blood, habitual bleeding from the nose, or from hæmorrhoidal vessels, as also where the natural excretion of blood is too profuse, the Liebenzell waters have acquired a well-merited celebrity; and so far they differ essentially from the Wildbad waters, as I have shewn in the preceding chapter. Used both inwardly, and as baths, they have, of late years, performed some striking cures, in cases of morbid sensibility of the stomach and intestinal canal, and have removed attacks of neuralgia, or *tic*, dependent on that condition of the digestive organs.”—(P. 76).

Deinach, a village situated in the heart of the Black Forest, five English miles from Wildbad, possesses two kinds of cold mineral springs, one being a carbonated saline water, and the other a carbonated chalybeate. The latter is very strong; “its taste is so intensely styptic, that it may be compared to that which is left behind on the tongue of a school-boy who wipes an inky pen with his mouth.”—(P. 78).

The temperature of all the springs is about 45°. Besides its efficacy in dyspepsia, Deinach has long been celebrated for the cure of insane patients, and several of that class, “including hypochondriacal and melancholic persons, were in the course of cure at the time I visited the springs.”—(P. 78).

Canstatt is a village distant only two English miles from Stuttgart, so that the invalid may live, if he prefers it, at the capital of Würtemberg, and drive or walk daily to the healing spring. The principal spring, which is that called the *Sulzrainquelle*, contains, in sixteen ounces of water, nineteen grains and a half of common salt, seven grains and three-fourths of Glauber, and nearly twice that quantity of Epsom salts, besides carbonate of lime, $\frac{3}{16}$ of a grain of carbonate of iron, and one volume and $\frac{11}{100}$ of carbonic acid gas. According to Morstatt, the temperature is from fifteen to sixteen degrees of Reaumur (66° of Fahrenheit).

Boll, the remaining watering-place belonging to this group, is twenty-five English miles from Stuttgart. The spring is a cold sulphureous one. “The water rises through a soil consisting of bituminous marl and a species of sulphureous gravel. It has a temperature of 54° of Fahrenheit, and its predomi-

* At p. 75, the quantity of solid ingredients in a pint is stated to be 43 grains, but from the quantities given in the table at the end of the work, this would appear to be a misprint for 43.

nant saline constituents are Glauber salt, and the carbonates of lime, soda, and magnesia. There are traces of iron and manganese, and likewise strong indication of the presence of bitumen. Of its gaseous contents carbonic acid is the most prominent; next in quantity is azote; and lastly, sulphuretted hydrogen. From long experience it has been found that Boll proves of essential service in diseases of the skin, psora, and other deturpating complaints. Nocturnal pains in the bones from erotic diseases, carious ulcers of the legs, contraction of the limbs, and lameness, have been cured in so many instances by the application of this water, that its reputation in these respects is undoubted, and of long standing. As a depurative of the blood when in a vitiated state, I should consider the mineral water of Boll, taken internally, capable of producing the most happy results. This view of its virtues, which I formed on a serious consideration of its composition, induced me to recommend it to an officer in the Würtemberg army, who, such was the ill condition of his blood, could neither bear a scratch, nor the slightest cut of his skin, without suffering from festering sores, which would continue open and angry for several weeks. This peculiar state had been brought about, partly by high living, and partly by early debauchery."—(Pp. 85-6.)

He was cured in two months, but complained of the nastiness of the water.

The whole establishment at Boll belongs to the crown, and the cheapness of rooms and baths is quite astounding. The rent of a bed-room varies from one to three florins a week; that is, from twenty pence to five shillings. A bath in a private room is about a shilling, and half that sum on the ground floor. A very sensible man, a native of Würtemberg, and well acquainted with the English nation, said to Dr. Granville:—"If an English family, coming hither, will put up with table, wine, hours, and amusements, as they find them, they may live comfortably and excessively cheap; but if they mean to introduce English fashions and English manners, they will have to pay and smart for their whims, and yet miss many of the comforts to which they are accustomed at home."—(P. 88.)

The next group, the Saltzburghian Spas, consists of two only, Gastein and Hof Gastein, situated about eighty-five English miles south of Saltzburg. Gastein lies in a mountainous region, more than 3000 feet above the level of the sea, and possesses four principal springs, whose temperature varies from 115° to 118½°. The diseases in which Gastein has shewn its powers are nearly the same as those cured by Wildbad. Hof Gastein is a village which receives the superfluous and overflowing visitors of Gastein. Want of room compels us to pass on without noticing our author's well-written discussion of the merits of these waters; but we will just mention one merit of the place itself, which some of our readers will not be slow to appreciate: it is not so *hacked* as many of the German watering-places are. An Englishman, says Sterne, does not travel to see Englishmen; but at many of these Spas the crowd of British men is quite overpowering; at Gastein, on the contrary, at least for the present, the great majority are not subjects of Queen Victoria.

The Bohemian Spas form the fourth group, and are seven in number, consisting of Carlsbad, Marienbad, Egra, Pullna, Saidschütz, Seidlitz, and Töplitz.

"Carlsbad," says Hufeland, "is a remarkable example, that what has real intrinsic worth is superior to all changes of time, fashion, and theory. Unpleasant in taste, without the immediate enlivening powers of the carbonated waters, not promising much, according to chemical analysis, and having a purgative quality, consequently neither attractive to the senses, nor through the importance of its ingredients, but rather of late years opposing the predominant theory, it has yet unalterably maintained its great reputation, for a very simple reason—it cured patients whom no other remedy could cure, and that in spite of theory. And thus it will ever be the case:—*Opinionum commenta delet dies, nature judicium confirmat.*"—(Hufeland, p. 137-8.)

He said the same thing to our author some years ago at Berlin: when he asked the reason of the undiminished celebrity of Carlsbad, Hufeland replied, "*C'est qu'il guérit des maux rebelles à tout autre moyen curatif.*"—(Granville, p. 248.)

The principal spring is called the *Sprudel*, and its temperature is 167°. "Its prominent chemical character is that of containing a large proportion of soda in three different states of combination, namely, as *Glauber salt*, *carbonate of soda*, and *common salt*."—(P. 223.)

According to Berzelius, of 31½ grains of solid matter in a pint of the water, 28 are sodaic salts. More recent analysts have discovered iodine, bitumen, a kind of organic soapy substance, and sulphuretted hydrogen gas; but the first and last of these Dr. Granville considers doubtful.

The waters of Carlsbad, says our author, "exert their principal sanative action,—1st, on all chronic affections which depend on debility of the digestive organs, accompanied by the accumulation of improper secretions; 2ndly, on all obstructions, particularly of the abdomen, which, as Becher, the oracle of Carlsbad, observes, they resolve and disperse; 3rdly, on the aerimony of the blood, which they correct, alter, and evacuate, or drive towards the extremities of the body; 4thly, on calculous and gravelly deposits; 5thly, on many occult and serious disorders, the nature of which is not readily ascertained until after the partial use of the waters, such as the *douloureux*, spasms, rheumatism, and gout."—(P. 249.)

Dr. Granville observes that nearly two-thirds of the diseases to which man in his civilized state is subject, in a chronic and often painful form, may be relieved by these waters. Among the diseases in which his own experience warrants him in recommending them, he mentions those engorgements of the spleen, and that distended state of its vessels, which he asserts, and probably with justice, to be more common in women, especially of the higher classes, than medical men appear to be aware of.

The Rev. C. E. Hutchinson, whose narrative of a recovery from the *douloureux* we noticed about three months ago, has written a letter to Dr. Granville, in which he seems much nettled with our doubts as to the cause of his cure. He says the reviewer denounces all that he has said as false. This is a sad mistake of the reverend layman; the reviewer merely supposed him to be in error—in well-meaning, excusable error. We would bet a copy of the *GA-*

ZETTE against one of Mr. Hutchinson's pamphlet (large odds these) that nineteen dispassionate persons out of twenty will take part with us, and not, as Dr. Granville has done, with the angry narrator.

In some cases, of course, these powerful waters are contra-indicated:—"Let him who labours under hectic fever, incipient phthisis, or dropsy, avoid Carlsbad, for it would hasten his end."—*Hufeland*, p. 164.

We would willingly linger awhile over the agreeable and instructive pages of Dr. Granville; but this review has already overstepped the usual limits of our notices. We must therefore break off abruptly, and pass over Töplitz and Egra, which with Carlsbad, says Hufeland, form the Bohemian *Kleiblutt*, or trefoil; nor must we speak of the glorious *Kursaal*, at Brückenan, nor Marienbad, the Garden-Spa, nor Selters with its million of exported jugs, nor Wiesbaden with its princely hotel, nor the other Nassau Spas sung of by the Old Man of the Bubble-book.

One thing, however, we must not omit to say. The maps are useful, and many of the wood-cuts are exceedingly good. Perhaps the best are the one of the Fürstenbad already mentioned, and the one at p. 146, representing a fountain at Saltzburg. To conclude: we would recommend those, if any such there be, who doubt the virtues of mineral waters, to read this work, and then extending their studies to the accumulated evidence of ages*, let them renounce their chemical scepticism. Perhaps one cause of these virtues may be, as Hufeland and Dr. Granville suppose, that the heat of thermal springs is combined more intimately with the water than when it is warmed by fire; to which we may add, that mineral waters probably contain ingredients which chemistry has not yet learned to appreciate; but whatever may be the cause, the effect is certain.

"Desine quapropter novitate exterritus ipsa
Exspuere ex animo rationem: sed magis acri
Judicio perpende, et si tibi vera videtur,
Dede manus: aut, si falsa est, accingere
contrà." *Lucret. i. 1039.*

* A hundred and ninety-eight works had been published on Carlsbad and its springs at the end of 1836.

MEDICAL GAZETTE.

Saturday, October 13, 1838.

“*Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri: potestas modo veniendi in publicum sit, dicendi periculum non recuso.*”

CICERO.

ON THE BEST MODE OF CONDUCTING MEDICAL STUDIES.

THE writer who gives advice to medical pupils as to the best method of pursuing their studies, may either suppose them to be limited in time and money, and consequently desirous of laying out both to the best advantage; or, that they wish to become finished practitioners of the highest class, without regard to time or expense. Some introductory lectures suppose the latter; and the attention of the pupil is consequently directed to the extreme importance of certain auxiliary branches, such as medical jurisprudence, and the utility of zoology, geology, and mineralogy. Now the advice which we shall venture to offer to pupils in the present article, will be chiefly addressed to that large class who come to London for two years and a half only, in order to study physic and surgery as they best may, and then pass their examinations at the College of Surgeons and Apothecaries' Hall.

We may make the preliminary observation, that if the length of time devoted to ordinary medical education is supposed to depend on the pecuniary circumstances of the parties, it is not a little curious that it should be so much shorter in England than in France, Austria, and other countries, where comfortable incomes are far more rare. This may proceed from two causes; either from the period of two and a half years, short as it is, appearing long by comparison with the periods previously enjoined; or from the five years' term

of apprenticeship being erroneously supposed to be identical with five years of education.

This leads us naturally to a topic of advice addressed not so much to pupils as to parents. The Worshipful Company recommend in their regulations, that the apprenticeship should not begin till “the youth has attained his seventeenth year, and that he should previously have received a sound classical education, and have been instructed in the elements of mathematics and natural philosophy, and have acquired a knowledge of the French, and, if possible, the German languages.” To this they add, that during the apprenticeship the pupil ought to become “acquainted with the nomenclature of the profession, the manipulations of pharmacy, and the elements of osteology; whilst opportunities should be afforded him of watching the progress of disease, and of noticing the effects of remedies.” If parents would take care, previously to binding their sons to an apothecary, to bring up their education to the level of these judicious suggestions, and then refuse to allow them to be degraded into mere powder and pill makers, but demand that their education should be continued during their apprenticeship, their progress when studying in London would be far greater than can be expected under existing circumstances.

The difference between lectures falling on the dull ear of a mere counter-drudge, and eagerly devoured by a genuine student, is infinite. To learn quickly one must already know much, and knowledge is most zealously sought for by those who have got over the first difficulties attendant on acquiring it:—

“*Quo plus sunt potie, plus sitiuntur aquæ.*”

We wish that the Court had likewise recommended that the lectures on botany and chemistry should, when possible, be attended during the first half of

the apprenticeship, and had allowed the pupil, on the commencement of more pure medical studies, to pass an examination once for all in these ancillary sciences, as he is permitted to do in Latin medical classics.

The student, however, who has not attended botanical lectures till he comes to town, will find that the Regulations leave him the choice of doing so during either the first or second summer session. We strongly recommend him to adopt the former alternative, if he remains in London during the summer, as he is not enjoined to attend any other course; whereas in the second summer session he will be occupied by midwifery, with the diseases of women and children, forensic medicine, and the medical practice of an hospital.

It is much to be wished that the Court would define what they mean by botany, so as to prevent the student from spending too much time in the endless details of this science; or that they would even sanction some manual containing a brief account of the elements of botany, and a description of the chief medicinal plants, and thus save the student both from bulky treatises and unsatisfactory vade-mecums. On the whole, the diligent pupil will not spend many of his hours on botany.

Chemistry is the first mentioned among the studies of the first winter session: it is certainly of more importance than botany, and, accordingly, has twice as many lectures allotted to it—a hundred instead of fifty. This is a fascinating science: but the zealous pupil must recollect, that if he wishes to become—we will not say a chemist, but even a chemical student of any pretensions, he must either sacrifice more important pursuits, or must extend the period to which we have supposed him limited. Here, again, it would be desirable that the Worshipful Company

should direct the student to confine his reading to some authorized manual, and substitute an examination in this work, with the performance of some easy experiments *coram curiâ*, for the undefined examination now dreaded by the student. We are hardly sanguine enough to hope that the ordinary pupil will be able to recollect the substance of a hundred lectures; but there are some prominent points which it is to be hoped even the more careless will not forget. Such are the tests for poisons, a list of the chief incompatible substances, or those which should not be prescribed in conjunction, the composition of the animal fluids, and the use of the barometer and thermometer.

The next subject on the list is anatomy. During his first winter session the pupil will attend lectures on anatomy and physiology, and anatomical demonstrations; during his second winter session he will attend the same courses, and is also required to dissect; during his third winter session he is again to dissect. We request our younger readers to observe that although the quantum of anatomical study here required may appear to them to be considerable, and may possibly be sufficient for the exigencies of general practice, yet that it is wholly inadequate for the real surgeon. They may answer, perhaps, that something more is required by the College; but this again they will find insufficient, if they hope ever to use the knife with safety and confidence. In fact, the quantum of dissection required in the education of the genuine operating surgeon is so great as not to come within our present scope; for we could no more expect it to be crowded into the space of two and a half years, and those years filled with other studies, than we could hope to see five harvests in the same time. Let the student, while dissecting, not omit to make

some preparations: they are useful to him while making and when made; a good refresher to his memory, and an excellent certificate of his industry.

The remaining subject to be studied during the first winter session is *materia medica*, and therapeutics. Nothing can be a better introduction to the practice of physic than this subject, if, indeed, we do not rather regard it as the practice of physic itself, seen under another point of view—the reverse, as it were, of the tapestry, where the figures can be made out, though the colours are not very clear. In treating of inflammatory diseases, for instance, the physician says, “Here we use purgatives, and especially the saline ones;” and in treating of the neutral salts, the lecturer, if he be a practitioner, (which he ought to be) will mention their especial use in the pyrexia. Hence, in addition to the history and properties of each drug taught in this course of lectures, the principles of medical treatment are impressed on the hearer’s mind. This, indeed, is implied in the very title of the course; it is not only on *materia medica* alone, but also on therapeutics. We would here caution the young beginner not to run off with the convenient but erroneous theory, that half a dozen medicines are sufficient for practice. They may be sufficient, perhaps, for some kind of practice, but certainly not for the best. We read, indeed, of pharmacology contracted by the French surgeons into the slender span of “*aqua, acetum, vinum, hordeum, nitrum, mel, rheum, opium, stibium, ferrum, ignis.*” (Young’s *Med. Literature*, 2nd edit., p. 452.) But this was probably done in a time of extreme necessity, and is to be quoted rather as a curious instance of what may be done by ingenious indigence, than what should be done by unfettered opulence.

As the student makes progress in the art of healing, he will find not only that it is right to know the properties of a great number of powerful remedies, but that many drugs denounced as superfluous by unpractical men, are useful—so that even quince seeds have their merits.

In his second winter session the student will attend his first course on the principles and treatment of disease. This is the most important of all the subjects he has to go through, and will demand a corresponding zeal. Lectures, books, and hospital attendance, all contribute their share of information. The notes taken in the hospital should, at first, be confined to a few cases, and the pupil will do well to look out for similar ones in systematic authors, or better still in those who have written on single diseases, or single classes of disease. The clinical lecturer, if applied to, will advise him as to the cases which should first occupy his attention; in default of such advice we should recommend the first half dozen to consist of fevers, simple or eruptive, and inflammations of the lungs or pleura. It would be desirable, if possible, that some period should be appropriated exclusively to medical attendance on an hospital, and the clinical lectures there delivered—assisted, indeed, by books, and by attending patients at their homes, but unincumbered by any other lectures. The study of practical auscultation would advantageously fill up a portion of this time. There are many pupils, however, who might contrive to do this, and with infinite advantage, after their examinations are over.

When attending the practice of surgery, the student, whom we are now more particularly addressing, will recollect that few of the great operations will probably fall to his lot; and it is to

be hoped that, as an honest man, he would not venture to perform them with an education of two years and a half. What is called minor surgery, however, will be his daily business; and his dexterity in bleeding, bandaging, passing the catheter, &c. &c., will contribute much to his reputation, his comfort, and his income.

The Practice of Midwifery, which the student will attend during his second summer, and his third winter session, is in one respect better taught than either the Practice of Physic or of Surgery; as it is, we believe, the universal custom for the lecturers to give cases to their pupils. The pupil, of course, renders an account to his teacher of the progress of the patients entrusted to him, and receives the benefit of his advice in all emergencies. Hence the pupil who contrives to learn nothing, or next to nothing, from a course of obstetrical lectures, must be an idler of the first water, and will learn little, we fear, anywhere else. When we add to these observations, the fact that midwifery is one of the readiest, or perhaps the very readiest, passport to success in our profession, we shall see ample reasons why this branch of study should not be, and is not, neglected.*

The pupil who attends indigent patients at their own homes, must recollect that the first rule of medicine is, *saltem non nocere*; that in doubtful cases he must not run the risk of aggravating the symptoms by powerful but inappropriate treatment, and must rather do nothing, than do harm; and if he has forgotten the dose of a remedy, he must take care to be

below rather than beyond the mark. Above all things, we would say to him, do not be harsh to your patients. They are poor and sick, and perhaps stupid; they do not understand your questions, nor, perhaps, you their answers. Bear with them; learn the vague dialects of poverty and ignorance; and when occasion serves, be the interpreter between those who speak so rudely, and the fortunate possessors of a more graceful language. Do not snatch a hasty glance at your patients, and then run off, as if you had half the practice of London on your shoulders, but consider each case with due attention. The pupil who, on entering a sick room, is in such an exceeding hurry that he has no time to sit down or take off his hat, had better wait, as the vulgar say, till his hurry is over.

The last branch of study that we have to notice is Forensic Medicine. This consists entirely of the most difficult and curious points in medicine, and the ancillary sciences, turned into problems, on which life, and liberty, and property depend. The pupil will admire, but cannot, properly speaking, study Forensic Medicine as a whole. Some points, indeed, he will retain; but to be qualified to give an opinion on medico-forensic topics in a court of justice, it is requisite that the witness should be a consummate physician, or surgeon, or anatomist, or chemist, as the case may demand.

Three more observations, and we have done. The first is, that the pupil who intends to profit by his sojourn in London must recollect that he does not go to lecture, nor to his hospital, in order to criticise, to object, to ask captious questions, or, in fine, to teach his teachers,—but to learn.

The second is, that he must make the hospital, as far as attendance on lectures will allow, his constant place of resort,

* It might, however, be cultivated with still greater diligence, and probably would be, if a midwifery board of examination were established. This has often been recommended, and has the support of Sir Astley Cooper, in his late evidence before the Committee on the Medical Relief of the Poor.

his second home; for it is the practice of physic and surgery that he has come to town to learn, and they are learned by seeing. Hence it is most advisable that the pupil's lodging should not be more than a few minutes' walk from this great scene of his studies.

Lastly, he must never forget that progress is made not by a few great efforts, but by a repetition of small ones:—the maxim of one of the most eminent of artists was, *Nulla dies sine lineâ*; and the medical student will do well to adopt it.

GLASGOW EYE INFIRMARY.

CLINICAL LECTURES BY DR. MACKENZIE.

September 29, 1838.

Iritis Sympathetica.

I OCCUPIED your time during last lecture with the narration of six cases of sympathetic iritis, and with a few general remarks on this affection. I am now about to draw some conclusions from those cases and other similar ones recorded by authors, and purpose to arrange what I have to say under the following heads:—

1. The kind of injuries which, affecting one eye, are apt to induce sympathetic inflammation in the other. 2. The date at which attacks of sympathetic iritis, or retinitis, are apt to occur. 3. The subjects in which this disease is generally observed. 4. The exciting causes of sympathetic iritis. 5. The symptoms, local and constitutional. 6. The nature of the connexion by means of which this sympathetic inflammation is brought on. 7. The diagnosis. 8. The prognosis. 9. The treatment.

1. The injuries which, affecting one eye, are most apt to excite, after some time, sympathetic inflammation in the other, are penetrating wounds, inflicted by cutting instruments, or by the forcible projection of splinters of iron or stone, or the fragments of percussion caps. A mere blow on the one eye (for example, with a stick) has been known to impair the other sympathetically; but in general it is from penetrating wounds that the disease we are now considering takes its rise. Sometimes the wound is inflicted by such an

instrument as a chisel or screw-driver, as was the case with Finlay, so that there can be no suspicion of any thing being lodged within the eye; while, in other instances, the suspicion is strong, or there is an absolute certainty, that a foreign body has passed through the tunics, and lies there unextracted. Sympathetic iritis has been known to occur both where the foreign body has been extracted immediately after the receipt of the injury, and where it has lain for weeks within the eye.

The injuries we are now speaking of are sudden and violent. They are generally attended by a loss of part of the humours, and by an extravasation of blood into the interior of the eye. The parts divided have generally been the cornea and iris, with a small part of the sclerotica and choroid. The junction, in fact, of the cornea and sclerotica, and consequently the annulus albidus of the choroid, is the place which has been wounded in most of the cases which I have seen. I think sympathetic iritis is more apt to be excited if the wound has been followed by a protrusion of the iris, and such a cicatrice of the cornea and sclerotica as keeps the portion of the iris not involved perpetually on the stretch. If the wound has been so extensive as to divide or lacerate the retina, sympathetic inflammation is probably still more apt to occur. The injury which the lens suffers in such cases, and the traumatic cataract which follows, have little or no influence in causing sympathetic disease. A wound which implicates merely the cornea and lens, or even a wound of the cornea with simple prolapsus iridis, is not apt to excite sympathetic iritis. I have never known any of the operations for cataract bring on this affection; not even when, after that of extraction, the iris protruded, and the cicatrice which followed caused dragging of the opposite side of the iris, have I ever seen sympathetic inflammation. These facts, then, would lead us to conclude that injuries of that part of the choroid called the annulus albidus are most apt to cause sympathetic iritis. If, along with a wound of that part of the choroid, there is a loss of part of the vitreous humour, and a protrusion of the iris, I should dread an attack of sympathetic inflammation; especially if, about the time of the cicatrization of the wound, the patient began to use the good eye in earnest, committed any irregularity in diet, over-fatigued himself, or suffered from mental excitement or distress.

II.—Were we to judge of the period of time which generally elapses between an injury of one eye and sympathetic inflammation manifesting itself in the other,

from the six cases which I related formerly, as having occurred in the practice of this infirmary, we should say that five weeks was the most frequent period; for in Mill, the sympathetic disease came on six weeks after the injury; in Paterson, the period was three months; in Moore, one month; in Downie, five weeks; in Finlay, five weeks; in Gartshore, four or five weeks. In three out of the six cases recorded by Mr. Lawrence, the period is not mentioned; in the other three, the periods were a few weeks, five years, and soon after six weeks. In Mr. Wardrop's two cases the periods were three weeks, and one year.

III.—The subjects of sympathetic iritis have most frequently been, in my experience, men employed in iron-works. At the time when their eyes were injured, their general strength was not impaired, but from their habits of life, and especially from their liberal use of spirits and tobacco, their constitutions were in an artificial state, very unfavourable for throwing off any inflammatory disease. Hence it appeared to be, that the iritis degenerated into the arthritic variety, and proved so intractable. In some of the cases I have seen, the sympathetic inflammation was modified by scrofula, a modification scarcely less troublesome than the arthritic. In one of our cases, Dr. Kennedy observed that the wounds made in bleeding the patient at the bend of the arm generally suppurated; which led him to inquire whether a syphilitic taint might not be present. The patient acknowledged having had some primary syphilitic symptoms before he received the injury of his eye; but he had no sore-throat nor eruption, and the eye, sympathetically inflamed, shewed no peculiar indications of syphilis.

IV.—It sometimes happens that the patient is unable to specify any exciting causes for the sympathetic attack; but, in other instances, causes of this kind are distinctly mentioned. For example, in Finlay, the exciting cause was manifestly the reading, for three or four hours together, in a book printed in a small type, and in one of Mr. Lawrence's cases, the eye had been incautiously worked. The wounds of the eye, which are apt to give rise to sympathetic iritis, commonly take from a month to six weeks to cicatrize. Whenever they are healed, the patients are apt to re-commence their usual employments and modes of life; and then it is that the exciting causes of the sympathetic disease come into play.

The same sort of exciting causes which produce the first attack of sympathetic inflammation, also bring on relapses when

the patient is recovering; and it is generally by a succession of relapses that vision is ultimately destroyed.

V.—The local symptoms of sympathetic ophthalmia are those of iritis, passing rapidly into amanosis and atrophy of the eye. Not unfrequently the first symptom is dimness of sight. This is rapidly followed by zonular redness around the cornea, dingy greenness of the iris, flexibility of the cornea, bogginess of the sclerotic, opacity of the capsule, greenishness of the lens, varicosity of the rectal vessels, the presence of red vessels ramifying over the surface of the iris, contraction and adhesion of the pupil, puckering and bolstering forwards of the iris, and total insensibility of the retina. The pain is very variable; for in some it is slight, as in Gartshore, who said she had had no pain in the eye sympathetically affected, while in others it is severe, as in Finlay. Photopsia is a usual symptom about the commencement of the attack. In some there is great intolerance of light, as in Paterson; in others, there is little. At length, the shrinking of the eye-ball, and especially of the cornea, is very remarkable. In one of Mr. Lawrence's cases, both cornea had shrunk to the size and figure of a barleycorn placed horizontally.

There can be no doubt that retinitis forms a part, and a chief part, in all cases of sympathetic ophthalmia. Perhaps retinitis occurs first, and added to it is the iritis. The early loss of vision shews that the retina is deeply implicated from the very commencement. The flexibility of the cornea, and softness of the sclerotic, indicate the vitreous fluid to be lessened in quantity. The changes which are visible in the capsule and in the iris are plain indications how far these textures are affected.

Sympathetic iritis is generally an inflammation of that description which is called *unhealthy*. It sometimes resembles scrofulous internal ophthalmia; more frequently it resembles what the Germans call arthritic ophthalmia. The symptoms are often such, that one skilled in German ophthalmology would at once say, here is arthritic iritis. I have often observed to you, that if we use the term *arthritic* merely as a conventional one, to express a certain variety of eye disease, characterized by certain signs, this may be allowed; but if by arthritic is meant strictly *gouty*, applied to the cases we are now considering the term is incorrect. The subjects of sympathetic iritis may have some peculiarity of constitution, produced by their mode of life, and by the nature of the ingesta to which they have habituated themselves; but these are not

sufficient grounds, I think, to suppose that they are labouring under the gouty diathesis. It is more probable that the particular textures of the eye which are affected, and the modes in which these textures are suffering, produce the peculiar symptoms which present themselves so strikingly in such cases, and which the Germans choose to call arthritic.

Amongst the constitutional symptoms we may mention quickness of the pulse, thirst, a marked buffy coat on the blood drawn from a vein, a pallid complexion, and obstinate constipation. A degree of ill health, in fact, has generally resulted from the confinement, want of exercise, and medical treatment necessary for the cure of the original accident; and in this debilitated state the patient is attacked by the sympathetic disease.

VI. The fact, that disease in one eye is apt to be followed by similar disease in the other, has long attracted attention. Inflammation, cataract, and amaurosis, have especially been observed to occur in this way, from what is termed a *consensus oculorum*.

Mary Young (No. 8266), who is at present attending as an out-patient, presents a curious instance of inflammation passing from the one eye to the other. Several years ago she was affected with trichiasis, xeroma of the palpebral conjunctiva, and thickening and opacity of the left cornea. At that time the right eye was perfectly well; but within these few months we have the same set of symptoms in the right eye, only in a less degree, which we had formerly in the left. The corresponding eyelashes are inverted, the corresponding part of the conjunctiva has become dry, and the corresponding portion of the cornea is opaque.

Jess Gemmel (No. 6234), and John McBrair (No. 8561), two patients at present on our list, afford instances of sympathetic amaurosis, and oscillation of the eyeball. In Gemmel the left eye was destroyed by a blow, and eight days after the right eye was found affected with oscillation, and a great degree of dimness of sight, but without inflammation. We know less of McBrair's history, as the injury which destroyed the sight of his left eye, and produced almost a complete absorption of the iris, occurred in childhood; but in him we have another example of sympathetic oscillation and amaurosis.

Dr. Albers (Himley und Schmidt's Ophthalmologische Bibliothek, ii. Band, iii. Stück, p. 169,) relates the case of a countryman, who, in a scuffle with his brother, was struck with a pitchfork in the right eye, whereby the cornea and iris were seriously injured. The wound healed up in such a way that the sight was not

entirely lost. In three days after the injury, the patient observed a diminution in the vision of the left eye, and a distinct opacity in the pupil was discernible. This increased so rapidly, that in eight days there were all the signs of a fully formed cataract. Half a year afterwards he was operated on by Professor Jung, of Marburg, but unsuccessfully, the patient remaining completely blind. Albers asks, if this case does not go to prove a decussation of the optic nerves; to which Himly replies in the negative. For suppose (says he) that the cataract, the sudden formation of which is very remarkable, was really a consequence of the injury, and not only so, but that the injury was the sole cause of the cataract, and did not operate merely in exciting a tendency already existing to opacity, we find similar appearances of *consensus* frequently in the corresponding teeth of the two sides, where no such decussation or nervous communication can be brought forward in explanation.

Notwithstanding this objection of Himly, it is generally acknowledged that those organs of the body are most apt to affect others, or in their turn to be affected sympathetically, in which the nervous system is the most developed; that there are no organs between which a sympathy in different states of disease exists so remarkably as the two eyes; and that there are no organs in which the nervous system is more developed, none in which the nerves of the opposite sides are connected in the same intimate way.

In the cases which we have been particularly considering, it is not improbable that the blood-vessels on the side of the injured eye, being in the state of fulness and inordinate action which attends inflammation, communicate to those of the opposite side, with which they have connexions within the cranium, a disposition to the same morbid state in which they themselves are. The ciliary nerves, also, of the injured eye may be the means of conveying into the third and fifth nerves an irritation, which may be reflected from the brain to the same nerves on the opposite side. I think, however, that the chief medium through which sympathetic ophthalmia is excited, is the union of the optic nerves. The researches of modern anatomists have tended only to confirm the conjectures of Newton (Opticks, query 15,) that the optic nerve of the one eye proceeding backwards, and meeting the optic nerve of the other eye, the two mingle their fibres, and partially decussate. It is extremely probable that the retina of the injured eye is in a state of inflammation, which is propagated along the corresponding optic nerve to the chi-

asma, and that thence the inflammatory action is reflected to the retina of the opposite eye, along its optic nerve.

VII. The history of the case will, in general, be sufficient to prevent any difficulty in the diagnosis. Sympathetic ophthalmia may be complicated with scrofula, and assume a good deal of the scrofulous character; or it may be complicated with syphilis, which an examination of the patient's skin and throat, and an inquiry into his previous health, will serve to elucidate. These complications, as well as the arthritic, will no doubt render the symptoms more severe; but they will scarcely influence the line of treatment to be followed.

VIII. The prognosis is so unfavourable, that it is our duty to guard the patient who has suffered an injury of one eye, against the exciting causes of sympathetic iritis, from the very first. When this disease is actually present, even the most active treatment is generally ineffectual. Indeed, I have never seen an eye recover from sympathetic iritis. Renewed attacks have, in every case, terminated in extinguishing vision. Mill is the only exception; but in him we cannot calculate yet on the final result. Any of the exciting causes I have enumerated would again rouse in him an inflammation, which all our applications might fail to check.

IX. Rest, antiphlogistic means, and the use of mercury, are the principal points of the treatment in sympathetic ophthalmia. These means, we have abundant proof, are not very successful. Still, to relinquish these remedies would be wrong.

There is a disease, Mr. Wardrop informs us, frequent in the eye of the horse, having the appearance of a specific inflammation, which usually first affects one eye and then the other, and almost always sooner or later destroys vision. It is known among some farriers, that, if the eye first affected with this disease suppurates and sinks in the orbit, the disease does not attack the other eye, or subsides if it had commenced in it. Thus they have adopted a practice of destroying altogether the diseased eye, in order to save the other; which is rudely done by putting lime between the eyelids, or thrusting a nail into the cavity of the eyeball, so as to excite violent inflammation and suppuration. Mr. Wardrop has frequently succeeded in saving one eye of the horse by adopting this practice; but he destroyed the eye by making an incision in the cornea, and discharging through it the lens and vitreous humour. "In some diseases of the human eye," says he, "where the disease makes a similar progress, first affecting one eye and then the other with complete blindness, the practice so successful in animals

might, by judicious discrimination, be beneficially adopted."—(*Morbid Anatomy of the Human Eye*, vol. ii. p. 139.)

The practice thus hinted at by Mr. Wardrop has actually been adopted, though with a somewhat different view, by Mr. Barton, of Manchester, in cases of injury of one eye with the fragment of a percussion-cap. You will find an interesting account of Mr. Barton's mode of treating such cases, communicated by Mr. Crompton, in the *MEDICAL GAZETTE*, vol. xxi. p. 175.

The accident in question generally occurs in shooting with percussion-caps, or in discharging them with a hammer—an amusement which is common with children. Mr. Crompton says, that in one of the cases which he witnessed under Mr. Barton's care, the vision of the uninjured eye was nearly lost from sympathetic inflammation, and adds that he thinks it most likely that there would have been a similar termination of the rest, if the plan of laying open the injured eye had not been adopted. Mr. Barton, it is true, opens the injured eye, with the view of extracting the fragment of the cap, on the presence of which he considers the sympathetic inflammation to depend. He not only opens the cornea with the extraction-knife, but cuts away a large flap of it with the scissors. He then applies a poultice, and waits till the fragment is discharged. In the cases published by Mr. Crompton, this practice appears to have not only relieved the patients of the pain they were suffering in the injured eye, but to have arrested the sympathetic inflammation which threatened the other. Is not this, then, good ground to adopt a similar plan, not only in cases where we have reason to suppose that some foreign body is lodged within the eye, but even in other cases, where the one eye being disorganized, and deprived of sight, the vision of the other eye seems likely to be lost by sympathetic inflammation? Where there is a suspicion of some foreign body being within the injured eye, there can be no question that Mr. Barton's practice ought to be adopted; but even in other cases, why should we hesitate to lay open an eye in which vision is extinguished, if the operation affords, as I think it does, a hope of our being thereby able to save the other?

AMPUTATION AT THE HIP-JOINT:

SECONDARY HÆMORRHAGE — DEATH AT THE END OF FORTY-EIGHT DAYS — AUTOPSY.

IN January, 1837, I was called to Michael Donnahue, æt. 25 years, a labourer, having a large tumor of the left femur.

He gave me the following history of his disease:—Nine months previously he had his left femur fractured, about six inches from its lower extremity, by the falling in of a bank of earth under which he was labouring. Before this was properly consolidated, he travelled a distance of about two hundred and fifty miles, on foot. Soon afterwards he noticed a tumor on the outside of the thigh, growing from the place of fracture. It increased rapidly, soon involving the whole circumference of the limb, and nearly the whole length of the femur. At the time when I first saw him, the tumor extended downward to the knee-joint, and upward to within three inches of the trochanter major on the outside, and within three fingers' breadth of the tuber ischii behind; measuring at its largest part thirty-two inches in circumference. As every means for arresting the growth of the tumor had been diligently employed without success, amputation seemed the only resort that offered a chance of recovery.

On the 14th January the operation was performed, in the following manner:—The femoral artery being compressed where it passes over the pubis, by my friend, Dr. Walker, a circular incision was made through the skin and tissues immediately subjacent, about four inches below the trochanter major; the integuments were dissected up, and a retractor applied. The muscles were then divided by a similar incision, and the bone sawed just at the lower part of the trochanter minor. The femoral artery and the profunda femoris were then immediately secured by ligatures. Considerable pieces of cartilage and of diseased cellular tissue were removed from the surface of the stump, and all the small arteries that bled were then secured.

On examining the stump the bone was found to be diseased; its cavity was filled with a reddish, gelatinous, and semi-fluid matter. The periosteum was thickened, and in some parts cartilaginous. I then proceeded, according to my original intention in such a contingency, to remove the bone at its articulation. Dividing the psoas and iliac muscles, and the muscles that come from the pelvis to be attached about the roots of the two trochanters, with a scalpel, and the insertions of the glutei and the capsular ligament with a bistoury, I was enabled with the latter instrument to divide the round ligament, and remove the head of the bone, without the least difficulty or delay. The articular cartilage over the head of the bone was thicker than natural, but the acetabulum appeared healthy. The hæmorrhage was not great, except from the

superficial vessels on the first incision; these for a moment bled profusely. Seven ligatures were required.

23d.—Dressed the stump; the four ligatures left out at the lower angle came away; the discharge much diminished and of good pus.

From this period until February 3d, nothing worthy of particular note occurred; the patient's appetite and digestion were good, and all the functions were well performed. On the 3d, the three ligatures that were left out at the upper angle came away. The man continued to do well, being free from pain and uneasiness of any kind, and able to move himself about without difficulty; the wound healing and the suppuration daily becoming less.

Feb. 15th.—A hard tumor is discernible in the left iliac region; he is troubled at night with a dry cough; pulse 110; the wound continues to heal; the discharge from the 16th to the 25th February not amounting to more than f. 5i. in twenty-four hours. In the meantime, the tumor just mentioned increased rapidly, presenting a hard, knotted, and uneven surface.

17th.—The stump is noticed to be slightly swelled; and on examination numerous hard bodies are discovered at various parts of its surface. The cough is severe, and not allayed by anodynes.

20th.—An unusual pulsation is observed about the end of the femoral artery, which appears to be aneurismal in character. Cold applications and compression made to the part, and strict rest enjoined.

26th.—The pulsating tumor, which had gradually increased in size, gave way after a severe fit of coughing. On arriving, I found him weak and exhausted from loss of blood. I proposed to tie the femoral artery, but the patient and his friends refused to permit me. The same means were therefore continued.

From February 26th to March 1st, he failed rapidly; his cough was more severe, his pulse more frequent. The tumor before mentioned extended to the symphysis pubis, and projected above the crest of the ilium; and the projections on the surface of the stump were greatly increased.

March 1st.—At one o'clock A.M. the bleeding recurred, and, the patient consenting, I placed a ligature around the femoral artery, just below Poupart's ligament. The pulsation immediately ceased. He lost no blood by the operation, and did not appear to be much affected by it. He continued to sink, however, and died on the evening of March 2nd, forty-two hours after the tying of the artery, and forty-eight days after the amputation of the limb.

On sawing through the femur and dissection mass longitudinally, the former was seen to be involved in its entire circumference, and from the condyles to near the trochanter minor; its cavity, too, on either side of the fracture, was filled with cartilaginous and semi-ossified matter. The largest part of the tumor sprung directly from the place of fracture: it consisted of alternate layers of cartilaginous and calcareous matter, disposed in form of radii. Other portions, entirely cartilaginous, sprung from the periosteum above and below. Numerous distinct pieces, from the size of a pea to that of a hickory nut, were found in the ham and above the tumor, which were only loosely joined to the original mass by cellular tissue.

On opening the stump, a narrow passage was seen leading directly to the acetabulum, having its surface callous, like that of an old fistula. The acetabulum itself was sound; the cartilage had not sloughed, and its cavity was nearly filled with granulations springing from its edges. The ends of the divided muscles were tipped with cartilage, and similar pieces were imbedded between the muscles. Just at the end of the femoral artery was a sack large enough to contain f.5iv., which had given way at its lower part. Above this the ligature was found about the artery; the inner coats of the vessel were divided by it.

On laying open the abdomen, a large cartilaginous and bony mass was seen filling up the hollow of the left ilium, extending downward into the cavity of the pelvis, and upward to near the kidney. The external iliac artery passed through it.

Both pleuræ were found studded with pieces of bone and cartilage, from the size of a pea to that of an almond.—*Recorded by Dr. Brainard, in American Journal of Med. Sciences, August 1838.*

NOTE REGARDING MR. GUTHRIE'S CLINICAL LECTURE.

Westminster Hospital,
Oct. 10, 1838.

THE reporter writing under the signature of "Idios" would feel obliged to the Editor of the MEDICAL GAZETTE if he would state, that Mr. Guthrie feels dissatisfied with the allusion to his bed contained in the last number of the Gazette, because he is represented as endeavouring to persuade his colleagues to use the invalid bed invented by him; and also, because he is said to recommend Desault's splints in all cases of fracture of the thigh. Mr. Guthrie emphatically declares, that he merely placed his "bed" in the wards to exhibit

its great efficiency, which his colleagues, if they have eyes, could see. He denies that any pain is occasioned by its use to any patient.

He does not employ Desault's splints in any cases of fracture of the thigh, except those arising from gun-shot wounds, where the matter would gravitate towards the hip-joint. On the contrary, he was the first to introduce Amesbury's apparatus into the Westminster Hospital. Mr. Knox's bed is not in use at the hospital, although Mr. Knox has written certificates as to its merit from the physicians and surgeons. Their experience of the efficacy of the bed has been derived solely from their private practice. Mr. Guthrie proposes that one of Mr. Knox's beds be purchased for the hospital, in order that a fair trial of the two should be made: until the result of such a trial be known, he shall continue to prefer his own.

The reporter was in error when he stated Mr. Knox's bed had been used in the Westminster Hospital; the hospitals in which it has been tried, and not found wanting, are St. Thomas's, and the Military and Naval Hospitals at Woolwich, Chatham, Haslar, and Plymouth.

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO HAVE RECEIVED CERTIFICATES.

Thursday, September 27.

Robert Francis Woollett, Usk, Monmouthshire.—Benjamin North Arnold, Birmingham.—John Charles Thomas Nicoll, Worcester.—Henry Stephens, Exeter.—John Morris Beynon, Haverfordwest.—Samuel Robert Kay, Bolton-le-Moors.—Charles William Otway, London.—John Jones, Dinas.—Charles Henry Claridge.—James Williamson, Northumberland.

LECTURES ON SURGERY,

DELIVERED AT ST. THOMAS'S
HOSPITAL,

BY THE LATE MR. CLINE;

With Notes.

[THESE lectures were written by Dr. Wilkinson when attending Mr. Cline's lectures, in the years 1787-88-89.

Extract of a letter from Dr. Wilkinson, dated Feb. 6, 1838:—"They (these lectures) are the results of six courses of lectures I attended at St. Thomas's, in 1787, 1788, and 1789; and I am in hopes I did not omit any interesting part of Mr. Cline's valuable observations. The one I had the pleasure of giving you is the repeatedly corrected copy."]

LECTURE III.

Fistula in Ano.—Diseases of the Testis: Circocoele, Sarcocoele, Varicocoele, Hematocoele.—Paracentesis.—Empyema.

Fistula in ano.—This is a fistulous orifice, extending by the side of the rectum, and most frequently having communication with the gut, originating from an abscess forming in the sides of the intestine. It is a very frequent disease, and puts on very various appearances. Sometimes the orifice is situated very near the anus, sometimes at a great distance; not unfrequently it is in perinæo. Sometimes very much on one side; at other times at the extremity of the os coccygis. We have frequently an aperture, two, three, or four inches from the rectum, yet in passing a probe it communicates with the gut. Sometimes there are more openings than one. After one abscess has formed, a second collection of matter may take

place, and make an opening in another part. Thus we have three or four openings in different parts near the anus, and not unfrequently all are found communicating with the intestine. It sometimes originates higher up the side of the intestine than at others. When near the anus, it mostly points externally, without any communication with the rectum; but if situated higher up, the patient, after having suffered extreme pain from the formation of the matter, is suddenly eased, from an opening into the gut taking place: the matter is discharged by stool; but it seldom stops here, as when there is a cavity of some size, it goes on ulcerating the sides of the intestine, and at last points it externally; when you have two openings, one in the skin on the outside of the other, in the intestine. Whether the opening has any communication with the intestines or not, it requires the same treatment, for these apertures are very seldom healed without being freely dilated. It is to be considered as an abscess in any other part, followed by a hollow cavity. During the formation of matter such applications will be necessary as will tend to relieve the painful sensations of the patient, such as fomentations, poultices, and the patient must more especially avoid costiveness. When the abscess is completely formed, then the fluctuation may be discovered externally, from the matter having passed under the skin; an extensive opening may now be made; or if suffered to go on till the matter is discharged, and the inflammation abated, it will be in a favourable state for the operation, and will be better than if performed immediately on the first discharge. It may be done in various ways. Some have made use of a pair of probe seissors for this purpose, introducing one blade into the sinus, the other into the rectum. This is rarely practised, owing to the pain it gives. It may be done by intro-

during a director along the sinus, then passing in a knife, which divides the rectum as it passes; this is dangerous, as you are liable to wound the opposite side of the rectum, on which account some use the syringotome, which is introduced up the fistulous orifice, and the finger conveyed into the rectum, which is not difficult, for the intestine is very thin, from the ulceration which has taken place on the surface; you easily get the probe through, then bend it within the rectum, bringing it out at the anus, (ligatures have also been used for this purpose). This may be easily done, when the sinus is only a little way up; but if as high as you can reach with the finger, it is very difficult to bend the probe, and to bring it out. The French surgeons use a flexible probe, bringing it out at the anus; then twisting it close to the gut, and leaving it to ulcerate. This is attended with a great deal of pain; but some persons dread the knife so much, as rather to suffer any pain than have it used.

The depth of the sinus should be ascertained by a probe, the patient leaning forwards against a table or chair. Mr. Pott has described a more convenient way than any of these; he uses a curved knife, with a button at the end of it. Having examined the extent of the fistulous orifice, you introduce the knife up the sinus, then carry your finger, oiled, up the rectum, placing it opposite the button of the knife: if there is no opening before, you easily pass the point through to the finger, and by bringing both down together through the anus, you completely lay open the rectum on one side. When the sinus is extending upwards in a direct line by the side of the rectum, this will be done at one stroke; but when the external aperture is situated at some distance from the anus, it will require a different mode of proceeding. We should then dilate the external part first. Having laid open the outer hollow part, you then divide the side of the rectum as before. After it has been laid open, lint should be introduced throughout the whole extent of the sinus; this separates the edges of the wound from each other, that they may not unite; it should remain until it separates of itself, by suppuration coming on; then all that is necessary is the introduction of small pieces of lint, between the external lips of the wound, to prevent its healing up close on the outside, before the granulations have filled up the cavity. The management of it after the operation is very simple, and is now usually attended with success. This mode of treatment has been fully explained by Mr. Pott, and he lays great

stress on proper dressings being used after suppuration has taken place. If there is more than one sinus, each should be treated in the same manner as a single one, by dilating them freely, throughout their whole extent. In these dilatations the sphincter ani is cut through, and is therefore incapable of performing its office; hence the patient for some time retains his faeces imperfectly; but in time the sphincter performs its function as before. Sometimes the matter that is forming extends almost round the rectum, near the anus; in this case it will be necessary to carry an incision through the integuments round the rectum, so far as the matter is extended. Besides, it will be necessary to slit up the rectum throughout the whole length of the sinus. In performing this operation you should not cut higher than you can reach with your finger; if higher, a very considerable hæmorrhage may arise from the hæmorrhoidal branches, and in such a situation it will be difficult to stop the hæmorrhage. In such cases a great deal of lint should be introduced, to press against the bones of the pelvis, which lint may be moistened with Spirit. Terebinth, which is a very good styptic, and some threads should be tied round these dossils, so as to withdraw them readily if necessary.

This is a complaint frequently accompanied with some other diseases of the parts, which in such cases renders the complaint very unmanageable. Sometimes there is a diseased prostate gland, on account of which inflammation is taking place in the contiguous textures; an abscess is formed in the cellular membrane, which makes its way into the rectum; in which case it is sometimes impossible to heal the wound, for where there is a diseased portion at the bottom of the wound, it will never perfectly close; also if there is any extraneous substance, as where a person swallows a bone, which, when it gets into the rectum, is forced through the coats of the gut by the forcible contraction of the surrounding muscular fibres getting into the cellular membrane, and occasioning an abscess to be formed. I have known, on opening an abscess of this kind, a piece of bone has come out. In another instance, where I had a good deal of difficulty in healing a fistulous orifice of this kind, there passed out a round calcareous substance, about the size of a hazel-nut, rather of an irregular surface; the wound soon after granulated and healed. Whence it originated is uncertain, but in all probability it occasioned the formation of matter, and protracted the healing till it was removed. We have every now and then by the side of the anus, orifices so very

small as scarcely to admit the head of a common probe, which will continue in that state for some time, occasionally closing and opening. On examination, these are usually found only to extend about an inch, and have no communication with the rectum; if communicating with the external surface of the rectum, the dilatation of them is equally necessary. In some such cases, though you dilate the wound freely, it does not heal; the reason is, that there are some small sinuses which have not been discovered. Where dilatations have been made several times on the outside, all attempts of healing these wounds have been ineffectual, from want of dilating a small undiscovered sinus. In some cases, where the parts are backward in healing, stimulating injections are of considerable service; as syringing the opening with Tr. Myrrh., or applying lint, dipped into it, or into a weak solution of corrosive sublimate, which will stimulate the part, excite inflammation at once, and bring on a disposition to heal. During the cure, we should attend to the health of the patient, because the constitution is frequently in a very weak state.

Castration.—In describing the diseases of the testis, authors make use of various terms—as *circoceles*, *sarcocele*, and *varicocele*. By *circoceles* they mean rather an enlarged spermatic cord, without a diseased state of the testis itself. In those cases where the enlargement depends upon the spermatic veins, there is seldom any disease of the gland itself. *Sarcocele* is an enlargement of the whole substance of the testis, when its body becomes considerably increased in size, and is a firm solid substance throughout; there is no collection of fluid within, and it is hard: this is called a scirrhus testicle. Sometimes in this enlarged state of the testis it is no harder than natural; at other times it is much indurated. *Varicocele* is improperly applied to any disease of the testis, never requiring any operation to be performed, being simply an enlargement of the veins, which is generally prevented by supporting the part, and making use of proper evacuations. *Hamatocele* is a collection of blood either in the body of the testis or the tunica vaginalis. Every now and then there is an effusion of blood into the body of the testis, and a very considerable increase of its size, which is not afterwards absorbed. It is blood which forms the tumor; and sometimes, independent of the enlargement of the testis, there is blood accumulated in the tunica vaginalis.

It is only those diseases which produce an enlargement of the substance of the testis that require the operation of castra-

tion; this is various in its course, and the enlargement puts on various appearances. Its progress is generally slow. It sometimes arises spontaneously, at others from accidents, as a blow, when a gradual enlargement takes place, which goes on increasing, while at the same time the figure of the testis is still preserved; e. g. the body is flattened on the sides, and a little prominent anteriorly, which distinguishes it from the hydrocele, which last takes on a pyramidal appearance, very much rounded, and broad below. After it becomes very much enlarged it loses this form, and becomes equally prominent at the sides as anteriorly. The disease at first is commonly attended with very little pain, but this increases with the size. As the testis becomes enlarged we find an increase of the epididymis, which extends up the spermatic cord; this also becomes harder and larger than before, and that above the abdominal ring.

Some diseases of the testis seem to have no tendency to produce a diseased state of the cord; they are so soft as to give the idea of a fluid, and are found to be formed of a number of hydatids within the substance of the testis. These pulp-like feeling testes are not very infrequent, though not always from hydatids, but very frequently from the substance of the testis undergoing a change, in which it becomes soft, not much unlike brain in a putrid state. Of this I have seen several instances, in which cases it has very much the feel of hydrocele—a fluctuating feel, and has been sometimes punctured under an idea of there being a quantity of fluid collected, but without any discharge. There is one common appearance when this has existed long, whereby it may be distinguished from hydrocele, viz. the veins of the scrotum are considerably enlarged, putting on a varicose appearance, owing perhaps to a greater quantity of blood being distributed to these parts in a diseased state, which is never the case in hydrocele. The tumor is also much heavier than in hydrocele. In the hardened state of the testis, it is very easily distinguished by the firmness of feel from other diseases. Some of these enlargements of the testis are curable. Diseases of this organ are extremely frequent; and sometimes, where the enlargement has taken place to a considerable extent, you are able entirely to remove it. If originating from a blow, and unattended with pain, the patient generally finds great benefit from emetics twice a week. Topical applications used at the same time, as linseed poultices, and, if very recent, vinegar poultices, are also useful. Electricity is sometimes of service. If the parts

are in a more indolent state, try Sal. Ammon. Crud. c. Acid. Acet. vel Spt. Vin. (3j. ad 5j.); also bleeding by leeches. When emetics have abated somewhat of the pain, and yet have not reduced the swelling, mercurials are advisable, which, to a considerable extent, are frequently beneficial. Of this I have seen several instances where, at first, I did not expect any benefit; yet by the patient using it repeatedly, it has very much abated the swelling. However, many cases will not yield to mercury, as those enlargements wherein hydatids are formed, or when the testis has got into the former pulpy-like state; but in such testes as have not gone through these alterations, but are only enlarged, mercurials are of service. But there are some which have not appearances or symptoms by which we can with any certainty determine this; therefore we must first try what medicine will do, and when it has no effect, the operation should be performed. If it remains long the spermatic cord takes on diseased action, which extends along the cavity of the abdomen, and is ultimately fatal!

There is one species of enlargement of the testis where the organ may be saved by an operation without removing it; it is when the swelling has come on suddenly, with great inflammation, and violent pain. In all probability there is an abscess formed in the substance of the testis, which being punctured, will heal. If, on examination, hard tumors are found in the groins, as enlargements of the lymphatic glands or cord, within the cavity of the abdomen, the operation is objectionable.

The operation is a simple piece of dissection, all besides that is necessary is a needle and ligature. The patient should have the parts previously shaved, and be laid upon a table of a convenient height, his legs hanging down. The incision should be begun about the abdominal ring, or a little above; but where the spermatic cord is not enlarged, or the testis very large, at the superior part of the scrotum will be sufficient; it should be carried down to the bottom of the scrotum, a part of which many advise to be removed with the testis, from the idea that there will be so much skin hanging loose as to be troublesome; but this is unnecessary, for after removing the testis the skin contracts so much, that there is seldom any superfluous quantity. The incision should be made opposite the ring. When you have laid bare the spermatic cord, you may take a needle with a broad ligature, holding the spermatic cord up with the finger and thumb, passing the ligature underneath. I think it is useful not

to make it directly upon the cord, but to place a piece of lint or rag between, making the knot moderately tight, in order that you may have a perfect command of the ligature after the operation, for very soon after there comes on much tension of the surrounding parts. When you want to remove the ligature it gives a good deal of pain, and this substance is conveniently cut upon afterwards for the removal of the ligature. The first knot should only be drawn moderately tight, then cut through the cord below the ligature, which gives more command of the testis to be dissected out, when, from having only drawn the knot moderately tight, hemorrhage will take place from the spermatic artery. You then further tighten the ligature and make a second knot, which secures it from bleeding. The reason for making the first knot loose is, that you are uncertain of the pressure which is necessary. In including the cord, it always makes pressure on the nerves, which is the most painful part of the operation, and this may be avoided by only using pressure sufficient to compress the artery. To avoid the pain, some have recommended dividing the cord, and afterwards separately tying the artery;* but there are usually two arteries—one accompanying the vein, the other the vas deferens: besides, this will delay the operation; and the nerves are so small, that you have difficulty to distinguish them from the arteries, so that you may possibly include them; the small branches should be secured as they are divided. The testis being removed, the cord tied, and any other small branches secured, the lips of the wound are to be brought into contact by pieces of adhesive plaster: thus the greater part of the wound heals by the first intention. If the cord is very much enlarged, extending into the abdomen beyond the reach of the finger, the operation should not be performed, as it will be attended with no advantage; but when the cord is but slightly enlarged we ought to give the patient a chance of recovery by the operation, as I have known several do well, though the cord was harder and larger than natural; whereas, in some, where there has been no apparent enlargement or hardness of the cord after removing the testis, disease has taken place within the cavity of the abdomen, and the patient

* Notwithstanding Mr. Cline is averse to this mode of proceeding, it is undoubtedly the best, and is usually adopted at the present day, for the pain produced by tying the cord is much increased by including the vas deferens; and no good is to be derived from such practice.—C.

has died. Also, in three instances of patients whom I castrated, they had a return of the disease, of which they died: two were in this hospital; one a man aged 25. We cannot be always certain that an enlargement of the spermatic cord does not extend into the abdomen. We are in some degree of uncertainty as to the event of this operation in almost every case.

Paracentesis.—This operation becomes necessary when the abdomen is distended with water to such a degree as to impede respiration; also being sometimes recommended with a view of curing the patient, though probably attended with little advantage in that respect. It may be performed for water situated in the cavity of the peritoneum, or where it is collected in an encysted state, as in the ovarium. Adhesion sometimes takes place between the peritoneum and cyst, and has been supposed to be a cyst of water between the abdominal muscles and peritoneum, which could not be. The sign of fluid situated in the abdomen is the existence of a distinct fluctuation: we ought never to perform this operation if this is not evident. If there is much water, by placing the hand on one side of the abdomen and striking the other opposite, you will feel it undulate from side to side—more especially if it be *ascites*: if encysted (only found in women), when the cysts are of considerable thickness, and the fluid gelatinous, which is sometimes the case, the fluctuation is not so distinct; also in some cases there may be adhesions between some of the viscera on the fore part of the abdomen; hence, though a large quantity is accumulated, it cannot be distinctly felt. We should only venture to make a puncture when the fluctuation is evident. I have heard of one case where the operation was performed, and the water successfully discharged, though the fluctuation was much less distinct than usual. It was found that the intestines were adhering, but fortunately not at the part where the puncture was made. This operation is performed with a trocar and a silver canula, which should fit very nicely. Some use a canula with a spout to it: it is attended with great convenience; the water being carried at a greater distance from the patient is not so apt to wet him, and make him uncomfortable. The patient should be placed in a chair upright, having a double-folded sheet round the abdomen, to be held by assistants, one on each side, that they may draw it sufficiently tight to compress the belly, which not only facilitates the discharge of the water, but the moderate pressure on the contents of the abdomen prevents the

patient from fainting. The puncture is directed to be made midway between the navel and the anterior superior spinous process of the ilium, towards the left side, about the linea semilunaris. It is ordered at the left side for the convenience of the surgeon, and for the purpose of avoiding the liver. In the usual situation of parts, this would be a very safe one, for it would be some way on the outer side of the rectus. The only vessel in danger of being wounded is the epigastric, which is some way on the outer side of the rectus abdominis naturally, but in a dropsical patient it is different. The rectus muscle becomes expanded in a greater degree than the oblique or transversalis: this carries the edge of the muscles towards the sides, which brings the epigastric artery to about the above space, and it is therefore very liable to be wounded, which happened to myself once. This accident has happened several times before, but the cause was not known. One patient died of hæmorrhage from the spleen being wounded, as I was informed by Mr. Ford. As this is certainly a dangerous place for performing the operation, I always perform it on the linea alba, about an inch below the umbilicus, a very little on one side, in which way the instrument penetrates somewhat more easily. This may be done with the greatest safety, as there is no part there in danger of being wounded. I prefer making the puncture with an abscess lancet, which passes with great ease, while the trocar gives much pain, and requires considerable force. Having introduced the lancet, the water follows, which may be guided by introducing the canula with the trocar. For this purpose, the end of the trocar should be rounded like the end of a probe, thereby saving the patient a great deal of pain. There is a trocar contrived by Mr. André, with a lancet point and steel canula: this is very convenient, for the great ease with which it passes, but has one very considerable disadvantage—the canula is so small, that the water passes off extremely slowly, therefore it is tedious to the surgeon and very fatiguing to the patient; hence better adapted for tapping in the hydrocele. After the operation a flannel roller seven or eight yards long should be applied round the abdomen, and a plaster on the orifice. We are now in the habit of drawing off all the water, whereas it was formerly the practice only to draw off a part. But Dr. Mead, while physician of this hospital, considered that the faintness was produced by want of pressure, and ordered the whole to be evacuated, and the pressure supplied by a bandage. When the

dropsy is encysted, the operation is to be performed in the same way as in ascites, only you have a thicker substance to cut through; when in several cysts, you can only discharge part of the fluid—namely, from that which is opened. By repeating the operation several times, the patient becomes considerably diminished in size. When the patient is weak, the operation may be performed conveniently by laying her on one side, on the edge of the bed, or on the table; this is less fatiguing to the patient, and more of the fluid is evacuated than when she is in the upright position, in which case there will be some left in the hollow of the pelvis, which will not be removed. In ascites the operation is rarely repeated very often, patients seldom surviving its repetition several times, for they generally become debilitated, and after it has been performed a few times, it is generally followed by an inflammation of the abdomen. Instead of the orifice closing, it remains open, and the water is totally discharged, in which case inflammation always takes place in the cavity of the abdomen. It is not so in encysted dropsy. Inflammation is not so liable to come on, and the operation has been performed a vast number of times in some patients*. An encysted dropsy does not equally affect the constitution as that of peritoneum. It is a disease of a part originally small, and patients will go on for a greater number of years, from being tapped now and then. Of this we have numerous instances, and if it was inquired particularly into, those who have survived several operations have been women having encysted dropsies. There are no instances of a man being tapped any considerable number of times—seldom above four or five.

Empyema.—This operation consists in making an opening into the cavity of the thorax, to evacuate some fluid. In the empyema, where there is a collection of pus situated within the cavity of the thorax, it may be known from the fluctuation discoverable at the time; also from the preceding symptoms, where the patient has had pleuritic or peripneumonic symptoms, afterwards followed by a cough and difficulty of respiration, which gradually increases, so that the patient is incapable of lying on one or the other side—only on the side where the fluid is situated. Sometimes, in this case, the in-

flammation has been more general, both cavities have partaken of it, and pus is formed in both sides, when the patient cannot sleep in a horizontal position, but is obliged to sit upright, supported by pillows, and is assisted by leaning a little forward, thereby relaxing the abdominal muscles. When water is accumulated in the cavity of the chest, so far as to impede respiration, there may be the same occasion for performing the operation. For this purpose a knife and director are sufficient. The incision should be made midway between the spine and sternum, about the middle of the chest laterally, between the sixth and seventh rib; making it lower down would endanger the diaphragm, and if on the left side the heart, and further backwards, would be inconvenient, from the greater number of muscles. The integuments are to be drawn upwards before the incision is made through them, that the opening through the integuments and through the pleura may not correspond with each other, that we may more effectually close the opening after the operation, to avoid the access of air, which would produce fresh inflammation. The incision should be about two inches long, laying bare the pleura, after which the director may be introduced, (the pleura being very thin, is easily lacerated), thrusting it on to the inside*. If the lungs are adhering, it is unfavourable to make the opening there; but it should be made on another part. If not adhering, the incision should be dilated, making the opening about an inch beneath, near the superior edge of the lower rib, to avoid wounding the intercostal artery, which passes along the inferior edge; the director being allowed to remain in the aperture, which should be kept open, and the patient turned on the side in which the opening is made, the matter or water would soon be discharged, when the integuments should be suffered to return to their former situation, to prevent any exposure of the cavity, and the inflammation which would consequently follow. For if the wound was kept in an open state fresh inflammation would arise throughout the whole cavity, which would be fatal in a short time:—we had better be under the necessity of repeating the operation than keep the parts open.

Under favourable circumstances we find that though parts are gone into the suppurative state, the suppuration will cease, the small portion left will be absorbed, and the patient get well.

* Mr. S. Cooper, in his Surgical Dictionary, mentions cases where the operation has been performed twenty-nine times—forty-one—fifty-two—sixty-five—one hundred—one hundred and fifty-five—and, if it be possible to credit Berard, even six hundred and sixty-five times upon one woman in the course of thirteen years!—C.

* It is now generally recommended to divide the pleura cautiously with a lancet.—C.

CLINICAL LECTURES ON MEDICINE,

Delivered at the Meath Hospital, Dublin,

Session 1837-8,

By PROFESSOR GRAVES.

LECTURE II.

Acupuncture in Anasarca and Ascites—Examination of the received doctrine respecting Bright's Kidneys—Objections to it—Forget's Cases; Morrison's; Solon's—Valentin's Microscopical Examination of Bright's Kidney—Remarks on the daily progress of Erratic or Creeping Erysipelas—Chorea, use of Stramonium in—Chorea in a man seventy-two years old.

LET me direct your attention, gentlemen, to some cases recently admitted, more particularly to one of ascites combined with general anasarca. I do not mean to enter into the history or details of this man's case, as it is sufficient for my present purpose to state that the belly was enormously distended, and the integuments so tense that it was quite impossible to ascertain the state of the liver or spleen; his lower extremities were also greatly swollen. In a case of this kind you have little to hope for from the use of diuretics, for the system is so oppressed by the great quantity of the effused fluid, that it cannot make an effort adequate to effect its absorption. The first step in all such cases must be the removal or diminution of the fluid by means of an operation. In the first place, the fluid might be removed from the cavity of the peritoneum by paracentesis, and the general anasarca might be relieved by allowing the fluid to drain off through small incisions or punctures made with a lancet in various parts of the body. For many reasons, I did not consider this to be a proper case for paracentesis, and therefore determined to try the effects of acupuncture—a remedy frequently employed in this hospital during the last three or four years, and which, in some instances, has proved successful: I say in some instances, for there are too many cases of dropsy, in which the causes of the disease are of an incurable nature. Under favourable circumstances, and in a good constitution, the simple operation of evacuating the fluid by punctures made through the skin, has been, in itself, sufficient to effect a cure. Thus, in a lady, a general anasarca came on after fever, and resisted every form of treatment I could devise; but when I had made many fruitless attempts to produce absorption by means of internal remedies, another practitioner was called in; he tried acupuncture of the lower extremities, and succeeded completely. You perceive, therefore, that

although mechanical means are not addressed to the cause of the disease, and appear to be nothing more than mere palliatives, they nevertheless may sometimes effect a cure. You will find, in a late number of the MEDICAL GAZETTE, a very interesting letter from Mr. King, detailing the particulars of the treatment of a case of ascites by acupuncture. Here, as in the new method of treating hydrocele, the object was not merely to give a vent to the fluid, but to cause it to be effused into the subcutaneous cellular tissue, external to the dropsical cavity; in its new situation the fluid is not only more readily absorbed, but is useful in preventing a fresh deposition within the sac, outside of which the fluid now is, and on which it exerts a very considerable pressure. Mr. King made more than seventy punctures in the space of two or three months, and was perfectly successful. I must refer you to his letter for the very novel and instructive details.

As yet, I have had no opportunity of trying this plan in ascites, but I have seen acupuncture applied in anasarca on several occasions. I do not think the case before us one of those in which permanent benefit may be expected, but you have all seen that considerable relief has followed a single trial of the remedy.

Most of you have, I presume, witnessed the performance of this operation by Mr. Parr. The needle is passed with a quick motion through the epidermis and cutis, and pushed on until it enters about half a line or a line into the subcutaneous cellular tissue. The punctures are about three quarters of an inch apart, and mark the angles of imaginary squares extended over a considerable portion of the swollen lower extremities. As soon as a sufficient number of punctures has been made, the patient, if able, is directed to sit up and let the fluid drain off. In this way a large quantity of water is withdrawn gradually from the system, and at little or no inconvenience to the patient. While the patient is sitting up it will be necessary to envelop the legs in flannel to protect them from cold, and the feet should rest on a piece of perforated board, by which means they may be kept as dry as possible. It will be also necessary to smear the punctured limbs with fine olive oil night and morning, so as to prevent any bad effects from the contact of fluid. By adopting this simple precaution, you will greatly diminish the risk of erysipelas—an accident not uncommon in such cases, and not unfrequently attended with the most dangerous consequences. When the sick person is confined to bed and unable to sit up, a large piece of oil-silk should be placed under his legs, and they should be enveloped with plenty of finely-carded Georgia cotton

wool*, which is to be changed as soon as it becomes moist. This serves the double purpose of absorbing the discharge, and protecting the limbs from pressure. I look upon this operation as possessing many advantages over the usual mode of making incisions with a lancet, for there is less risk of bringing on erysipelas. Here is one of the needles generally employed by Mr. Parr, — you perceive it is about the size of an ordinary glover's needle, and of a triangular shape. The reason of its being made triangular is, that the puncture of such an instrument is less apt to close, for obvious reasons. The quantity of water which sometimes drains off from the punctures is very remarkable; you have witnessed the vast quantity of fluid which flowed after the punctures in the present case. When the dropsical swellings return, after a temporary cure, effected by acupuncture of the legs, it is not practicable, in most cases, to have again recourse to the remedy, for the subcutaneous cellular tissue becomes somewhat indurated, and less pervious, in consequence of the certain degree of inflammation which follows this operation: in such cases, some other part of the limb or surface must be chosen.

It is curious to observe the physiological effects of this simple remedy. As there is a communication between the cells of the cellular membrane all over the body, it is easy to conceive that the anasarous fluid may drain off through punctures in the extremities. It is more difficult to explain how evacuating the water through punctures in the lower extremities can diminish the ascites. There is no direct communication between the cavity of the peritoneum and the general cellular membrane of the body, as may be proved by the fact of persons being afflicted with ascites for months, or even years, without any oedema of the lower extremities ensuing. This fact is quite sufficient to prove that no direct communication exists between the abdominal cavity and the subcutaneous cellular tissue of the lower extremities, and consequently that the fluid of an ascites cannot be mechanically evacuated by drains established in the legs. Now, then, is the diminution of the ascites produced? By the relief which the general system experiences from taking off an oppressive load of fluid, by emptying the subcutaneous cellular tissue, the general disturbance is lessened, the energy of the absorption increased, and a quantity of the intra-peritoneal fluid is consequently carried off. It is unnecessary to say more respecting the treatment of this case. I shall only observe, that in cases of dropsy, when you have produced a large drain from the system, you must support the patient by means of

nutritious diet and wine, combined with full doses of opium*.

The next patient to whom I shall direct your attention is a man named William Barton, lying at present in the large chronic ward, for many years a soldier, and much exposed to the vicissitudes of climate in various foreign stations; he has also been affected with dropsy for the last twelve months. When admitted, he was labouring under confirmed dropsy, accompanied by bronchitis and bowel complaint. He had, in fact, general derangement of the mucous surfaces, with ascites and anasarca. The usual comforts of an hospital, rest, and attention to diet, were the only means employed for the first fortnight, and these proved so far successful that the bronchitis gradually disappeared, and the bowel complaint completely subsided. It was observed, at the period of his admission, that the urine was highly albuminous, and, in this point of view, the case is deserving of attention. He was treated successfully, and as the dropsical symptoms disappeared the urine became less and less albuminous, until at length it was quite natural. This man's urine was examined daily by Mr. Moore, of whose attainments as a chemist I can speak in the highest terms. As I have already remarked, the albumen wholly disappeared, and the urine again assumed its normal character. In this way the man continued for about a fortnight, and, being greatly interested in the case, I had the urine examined every second or third day, and watched the result with the closest attention. It remained still without a trace of albumen. On last Friday, the poor man being apparently convalescent, and walking about the ward, caught cold in consequence of a draught of air from an open window, was attacked with rigors and symptoms of feverish excitement, and next day we found him labouring under erysipelas of the face. While engaged in examining him I asked to see his urine. He said there was none in the vessel, but that he thought he could pass some; and accordingly he did pass about half a pint of healthy-looking urine, but we found it to be highly albuminous, and of the specific gravity 1027. Here, then, is a case which speaks volumes with regard to the pathology of albuminous urine. A man, labouring under chronic dropsy, presents himself for admission, and on examination we find his urine to be highly albuminous. Without any active measures, and almost wholly by the efforts of nature, the dropsical

* French wadding will not answer as well as the finely-carded Georgia cotton wool.

* This man's case was apparently so hopeless, when admitted, that none of the pupils thought it worth while taking notes of its progress. The operation of acupuncture was several times performed, and with the aid of the usual internal treatment, a struggle, protracted for several months, ended in perfect recovery.

symptoms gradually disappear, and the urine becomes *pari passu*, less albuminous, until at length it assumes the natural character, and ceases to exhibit the slightest trace of albumen. This natural state of urine continues for a fortnight, when suddenly he catches cold, gets erysipelas, and in the course of a few hours the urine is found to be highly albuminous again. Before this accession of erysipelas his urine was not only free from albumen, but was perfectly normal; in colour, chemical composition, and odour, resembled the urine of a person with a digestion subsisting on a very nutritious diet. The very hour the erysipelatous disturbance came on there is reason to believe that albumen again made its appearance in the urine; in a few hours it was present in great quantity, although the secretion had a high specific gravity and a deep colour, by no means usual concomitants of albuminous urine. After proceeding for some days in the ordinary way, the erysipelas took a most unexpected and singular turn, extending from the skin by the angles of the mouth to the inside of the cheeks and lips, and finally spreading by the fauces to the larynx, where it produced suffocation. Erysipelas does not in general attack internal parts by extension from the surface. When erysipelas on the scalp affects the brain it does so without creeping inwards through any of the cranial openings. In one case, however, which I treated, fifteen years ago, in the Old Meath Hospital, the erysipelas obviously crept in, *as was proved on dissection, by the orbit*; but this is very rare indeed, and so likewise is the extension of erysipelas from the face to the larynx.

This case gives me an opportunity of directing your attention to the phenomena of that form of erysipelas termed erratic. It is a curious fact that in the majority of cases this disease commences on the bridge or alæ of the nose. It is not of a plegmonous character, and does not engage the subcutaneous cellular membrane to any extent, except where it is loose, as in the eyelids; it depends on an inflammation of the corium, particularly its external layer, giving rise to heat and tingling pain, with more or less redness and a slight degree of elevation, particularly at the margins, where a kind of ridge points out the line of demarcation between the healthy and diseased skin. It is not in general dangerous, rarely requires any antiphlogistic measures, and almost always spreads according to fixed laws. It is usually symmetrical, and its course is, for the most part, uniform, commencing upon the nose, and spreading gradually over the head, neck, and trunk, in a manner which has not, as far as I know, been described by any author. It is comparatively a mild disease, and much less dangerous than

another form which attacks the face and head, terminating in extensive subcutaneous suppuration. The latter spreads rapidly, and without any regard to symmetry*; it is often accompanied by high fever, headache, and sometimes delirium and coma, and has attracted much attention from surgeons, as being one of the common consequences of wounds of the scalp, in persons of impaired constitution or irregular habits. But the form of erysipelas which we are now considering differs from this in many points. It generally commences on the nose, about the alæ, from which it extends gradually and slowly over the face, temples, sides of the head, nape of the neck, and back. It is not generally attended with violent fever, headache, delirium, or coma, rarely vesicates, and seldom or never ends in suppuration. Setting out from the median line at the nose it spreads over both the malar prominences, descends over the cheek, sometimes leaving the upper lip untouched, and arriving at the edge of the lower jaw, its downward course is arrested, and leaving the fore part of the neck free, it begins to spread in the opposite direction, engaging the eyelids, forehead, and temples. It does not in general attack the upper or under lip, or the tip of the chin, and this, with its sudden arrest at the edge of the lower jaw, gives to the face a very peculiar appearance. In this and similar instances much interest has been excited among you in watching whether the disease, in its descent along the face, would, contrary to my prediction, reach the front of the neck by way of the skin covering the lower jaw; as yet we have not seen it do so, which is a most curious and inexplicable fact. Having spread over the cheeks down to the lower jaw it then changes its direction, quits the median line still more, and proceeding laterally by the temples, ears, traversing the mastoid process, it arrives on the back of the neck. About this period it not unfrequently throws out little detached patches, which appear, as it were, insulated in the vicinity of the main tract. Having arrived at the interscapular space it sends off wings on either side towards the shoulder, passing over the latter and under the axilla, and descending along the back generally stops there on the loins. It never spreads equally before and behind, but occupies the back and shoulders in some, while in others it proceeds from the nape to the front of the neck, and thence to the sternum and anterior part of the chest. Occasionally it reaches both arms, but rarely, if ever, goes beyond

* In a former lecture published last year, in the MEDICAL GAZETTE, I have more particularly described what I have termed symmetry; it means a uniformity of outline and extent in the erysipelatous portions of the skin at either side of the median line.

the insertion of the deltoids ; as it advances, its progress, and the extent of surface which it involves, become every day increased, while, at the same time, the redness declines. It extends much more rapidly in the lateral direction than along the median line, and generally occupies about a fortnight in its advance. As I have observed before, it does not spread merely by continuity of surface, but often throws out little detached islands, and this is the reason why we cannot arrest this form of erysipelas by means of nitrate of silver. If you draw a line before it with nitrate of silver, it undermines, as it were, your line, and appears on the other side without any apparent retardation of its march. Having gone on in this way for a certain space of time, varying from seven to fourteen or seventeen days, and embracing a larger portion of skin on each successive day, it suddenly ceases, its cessation being in general accompanied by increased secretion from the skin, and abatement of the feverish symptoms. No author has noticed the very remarkable fact that the last day's march of erratic erysipelas is, in some cases, its longest,—it is, if I may use the expression, a forced one ; it then stops suddenly. But although the extent occupied daily thus increases until the moment the disease terminates, yet, for some days before that event, the parts newly seized are less and less intensely red, and on the last day, during which the greatest progress, or *longest march* as to extent, is made, the skin is but slightly tinged by the erysipelas. In other cases the progress of the erysipelas is different, and, as it approaches the period of its termination, its daily progress exhibits a daily diminution, both in extent and intensity. In a lecture, formerly published, I have spoken of the treatment of this form of erysipelas. Wine and quinine agree well after the first few days from its accession.

This man's kidneys were found somewhat enlarged, and at first I thought they were otherwise natural, but a further examination and maceration convinced us that the cortical substance was paler than usual. Increase of size, paleness, and, *perhaps*, a very slight softness of the cortical part, constituted the whole change ; there was no appearance of granulations either on the surface or in the substance of the kidneys. Does not this case, gentlemen, render it extremely probable that the general state of the constitution influences the appearance of albumen in the urine, more than any change in the structure of the kidneys, for here, the same kidney secreted, within a very short space of time, perfectly healthy, and very albuminous urine ? This case, indeed, seems to establish the conclusion which I have before advocated in the "Dublin Journal," that Bright's kidney and albuminous urine

are effects produced by the same general cause, operating, in dropsy, on the constitution ; in this point of view I shall consider them, and my opinion is further confirmed by a very remarkable case, published in the same journal, No. 36, January 1837, by Mr. Morrison, page 474, who makes the following observations :—

"In making a few cursory remarks on the preceeding case I may first direct attention to the albuminous state of the urine. At different periods, during the last five years, this fluid was examined by different practitioners, and found coagulable by heat and acids. Now, I believe it is nearly agreed, that the above state of urine designates a peculiar granulated structure of the kidneys. But here is a case, and it is the only one of which I am aware, that undeniably proves that albuminous urine may be voided even for years, without the existence of even a resemblance of such a structure in the kidneys. Drs. Hacket and Erskine, and Mr. W. Bell, who were present at the examination, remarked that the kidneys presented a perfectly natural appearance, except that of their blanched colours. I have no doubt that Dr. Bright's statements, relative to albuminous urine, will generally be found correct ; but I think the foregoing case will bear me out in saying, that exceptions to them will occasionally occur, and certainly it is right, and, in my opinion, not at all detracting from Dr. B., that the profession should know there are exceptions."

This is a subject concerning which I have so often written, that I am afraid of appearing guilty of a needless repetition ; its importance, however, will, I trust, prove a sufficient excuse for the following observations. If albuminous urine may be secreted by kidneys in no way affected with the change of structure described by Dr. Bright, then there is strong reason for disconnecting the two, and not considering them as cause and effect. Now, in confirmation of the above case related by Mr. Morrison, I myself have witnessed a dissection of a boy who had dropsy, with highly albuminous urine, after scarlatina, and in whom the kidneys presented a perfectly healthy structure ; and Dr. Forget, of Strasburg, has recorded several others. His seventh case*, says the reviewer, "is especially interesting, as it affords an indisputable example of a most complete *albuminaria* during life, when the kidneys were found to be *parfaitement sains, sans anémie et sans granulations*. The heart was hypertrophied and the mitral valve ossified. In Dr. Forget's eighth case the urine was albuminous, but the kidneys per-

* See "Medico-Chirurgical Review," by Dr. Johnson, (New Series), No. 56, p. 544.

fectly sound. This patient likewise had organic disease of the heart."

In Dr. Forget's second case of dropsy, with albuminous urine, the patient recovered, and the urine became healthy. If, then, kidneys of a perfectly healthy structure may and do secrete, and that in numerous instances, a highly albuminous urine, and if, as in the man who gave occasion to these remarks, Bright's kidneys may secrete a perfectly healthy urine, can we attach much value to an hypothesis which seeks to establish a connexion, as cause and effect, between Bright's kidney and albuminous urine? From the time this doctrine was first brought forward, I was led, by my own observations, to doubt its accuracy, and I now feel satisfied that it is incorrect. Let me conclude by repeating what I have said on a former occasion, that in dropsy, where a secretion of an albuminous fluid takes place into the serous cavities and cellular membrane in such abundance, it is easy to understand how the urine may be likewise impregnated with albumen, independently of organic alteration in the kidneys. No gland seems more liable to multiform and often sudden alterations of secretion than the kidney. At one hour healthy, deep-coloured, and of considerable specific gravity, mental motion, or an hysterical affection, may render it the next hour pale, aqueous, and very different in chemical composition. To-day, in consequence of indigestion brought on by error of diet, the urine may be loaded with lithates, and may contain purpuric acid; to-morrow the former have been reduced to their natural proportions, while the latter has entirely disappeared. Again, if a peculiar change in the substance of the kidneys is necessary, to give rise to the presence of albumen, how does it happen that much greater alterations take place, permanently, in that secretion, without apparent deviation from its natural structure? The kidney of the lithic acid diathesis differs not from the kidney of the phosphatic, and in alternating calculus we do not find the renal organization varying as the urine contains, at different stages, a superabundance of lithates, of phosphates, or of oxalates. Why should the secretion of a simple animal principle, like albumen, require a change of structure in an organ which can accomplish the formation of such a variety of products, retaining all the time its ordinary size, consistency, and colour? This reasoning, together with the cases adverted to above, leaves little room for doubt on the question at issue.

We have seen it assumed that *renal hyperæmia* of an active nature constitutes the change the kidney undergoes; I have already remarked that no two conditions of an organ can be more dissimilar than this hyperæmious

state, and the yellow granular degeneration forming the extreme specimens of the disease; and yet we are taught that each of these morbid conditions of the kidney, not only differing from, but opposed to each other, gives rise to the secretion of albuminous urine. I have already shewn that albuminous urine is often secreted by healthy kidneys; and Dr. Solon, who has lately published, at Paris, a very learned work on this subject, admits that in his twentieth case the albumen disappeared during four days, *at least*, before death, and yet the kidneys were hyperæmious. An acute and intelligent reviewer of Dr. Solon (*Lancet*, June 23, 1838), remarks, "In alluding to those cases, distinct from Bright's disease, in which albuminous urine is found, Dr. Solon justly observes that they in no wise disprove the connexion which may exist between the renal lesion, and that condition of the urine. The only fact," he continues, "capable of doing so, would be the existence of the renal disease, well characterized, without albuminous urine. Now, this has never been observed."

This I am very willing to admit, but draw from it a very different conclusion, *for to me it appears that the albuminous state of the urine is the cause of Bright's disease, and not the consequence.* In dropsy, a tendency to excessive secretion of albuminous fluid is observed all over the body, and in the kidney as well as in other parts; now as the secretion of urine takes place in extremely minute tubuli in the cortical substance of the kidney, and as its secretion is accompanied by the formation of various salts and acids, no wonder that a deposition of albuminous molecules should be separated by coagulation, and should remain in the secreting tubes, which they gradually fill and distend, and thus give rise to an obliteration of tissue, termed Bright's disease. This is a new, and, I think, a correct view of the subject, and is confirmed in a striking manner by the following microscopical observations very recently made by the celebrated Valentin:—

"It admits, no doubt, that the degeneration of the kidney, described by Bright, stands in direct proportion to the excessive quantity of albumen contained in the urine. It is not, however, yet discovered what may be the cause of this relation. Microscopic research, in remarkable cases, may be able to afford more accurate information on this point. For example, we found on the post-mortem examination of a boy, æt. 13, who, for a long period, had been afflicted with dropsy and oedema, and whose urine sometimes contained albumen in immense quantities, sometimes very little, not only effusion into the chest and abdomen, but remarkable granulation of the kidneys in the fifth stage. Both kidneys were excessively enlarged:

their greatest length was $3\frac{7}{75}$; their greatest breadth $2\frac{1}{2}$. This enlargement did not exist in particular spots only, but engaged the whole substance of the kidney, and was smooth and uniform, and similar to the increase of volume assumed by a well-injected organ. Externally were to be seen the solitary ashy grey specks; internally, the tissues, particularly the cortical, were tinged of a deep yellow colour. Microscopic examination shewed that, while the stretched tubuli uriniferi of the mamillæ were either empty or filled with a little fluid, the tubes of the cortical substance contained a yellowish grey mass throughout, so as to be rendered, in a certain degree, visible, as if injected. It only required a fine incision, in a clear light, to see in the most distinct manner the beautiful windings of the urinary canals in this state of injection, even in cases of moderate enlargement. The measurement of these, in the cortical substance, in the centre, was about 0.003500 P.⁵*; in the mamillæ 0.005400 P.⁵. Nothing abnormal could be perceived in the walls of the canals, nor in the substance placed between them. One kidney was finely injected. The distribution and diameter of the blood-vessels, as well as of the corpora Malpighiana, exhibited no irregularity. The mass which filled the incised canals, of a greyish-yellowish hue, consisted of irregularly granulated bodies of greater or less size, little molecular bodies, and round yellow little spheres. Similar appearances were found in the elongated canals, only in a less degree.

"If I am not much mistaken, this discovery in the kidneys goes far to prove that, in this case, the kidneys are only the receptacles of the diseased urine, and that they, on a cursory glance, have only the appearance of being diseased themselves, whilst, on the other hand, the diseased process of secretion must be sought for, not in the kidneys, but elsewhere; as, for example, in the blood, for it is well known that the urine can be secreted without kidneys."

There is an extremely interesting case at present in the chronic female ward; I allude to the girl labouring under chorea. Mary McDonnell, now 16, well made, and generally enjoying good health, has had several attacks of chorea. The first commenced seven years ago, and was attributed to fright. It was accompanied by aphonia, and lasted for some weeks. About three years since she was under Dr. Stokes's care, for a similar attack, but without any loss of voice; was leeches over the spine, and dismissed cured, after a seven weeks' stay in the hospital. On her last admission she was found to labour under chorea in an aggravated form, having involuntary motions of almost all the

voluntary muscles, including those of the face and tongue, the motions being rather increased at night, and depriving her of sleep. She had no headache or pain in the back; the heart's action was quickened, but normal; the pulse 108; bowels constipated; tongue slightly furred; considerable flatulence. The catamenia appeared about eighteen months ago, and have continued regular. This last circumstance is calculated to diminish, very much, the importance attached by some persons to menstrual irregularity as the cause of chorea. Here the menses were quite regular, and yet the symptoms of chorea were of an extremely aggravated character. Besides, the occurrence of the disease in males, and before the age of puberty in females, is quite sufficient to shew that the derangement of the menstrual function cannot be classed among the causes of chorea. In the case of a young lady, whom I attended some time ago, with Dr. Marsh and Mr. Mulock, the recovery was complete, and yet the menses did not appear until five months afterwards. I may observe, too, that in the case of this girl McDonnell there is no reason to suppose that the disease depends upon subacute or chronic inflammation of the brain or spine. It is essentially a disease of the nervous system, but there are no grounds for inferring that it is connected with inflammatory action. Chorea has been defined as consisting of irregular motions of the voluntary muscles, continued while the patient is awake, interfering with and deranging the efforts of volition. It bears some analogy to paralysis agitans, subsultus, delirium tremens, and similar diseases, but differs as to its cause, the period of life at which appears, the state of the sensorium, and many other particulars. It generally ceases during the hours of sleep, and in this way the system is enabled to recruit itself when fatigued by long-continued muscular action; but in the case of this girl the movements are increased at night, adding greatly to the distress of the patient, by depriving her of rest. The day after her admission she was ordered to take aperient medicine, to have her head shaved, and use the tepid affusion three times a day. Under this treatment some transient relief was experienced; the irregular action of the muscular system ceased for about half an hour after the affusion, but returned again, and the disturbance of sleep remained undiminished. The tepid affusion was tried with great care and perseverance, and totally failed, which is remarkable, when we recollect how extremely efficacious it proved in the case of the young lady before spoken of, and whom it saved from the most imminent danger. This is a proof, if proofs be wanting, of the vanity of hoping that we can find any remedy capable of always pro-

* The decimal numbers are referred to a Parisian inch, as unity.

ducing a given effect on any nervous disease. The patient was now ordered to take thirty drops of the solution of muriate of morphia, twice a day, and this proving ineffectual, the dose was increased to forty drops. This treatment was continued for three days without any benefit; on the contrary, the irregular motions became more violent, and the state of watchfulness unaltered. She was now directed to take, three times a day, a pill containing the sixth of a grain of extract of stramonium, followed by a draught containing a dram of spirit of turpentine. This was on the ninth; on the tenth she is reported to be much improved, and to have slept for some hours during the night. Her pupils, however, were greatly dilated, so that it was thought advisable to discontinue the stramonium for some time. On the twelfth she was able to resume the use of stramonium, of which she took four doses in the day, with marked improvement in her symptoms. The spasms were notably diminished, and she was able to enjoy four or five hours' comfortable sleep at night. The effect of the stramonium and turpentine was very striking, and the rapidity with which ease and comfort were induced, in place of inquietude and suffering, excited much surprise among you. I now regret, that in consequence of having given the stramonium and turpentine simultaneously, we cannot, with certainty, say to which the cure was owing: as the stramonium was also given in the other successful case, it is possible that it may have been the chief instrument of cure in both.

A question arises here, whether we could have effected a cure, in this case, by tonics? I think not; where the nerves of the whole system of voluntary motion are deranged, we cannot expect to derive much good, at least in the commencement, by the use of tonics. The remedies in which we can place most reliance, in such cases, are those known to possess the power of controlling spasmodic action. Among them, musk, turpentine, and stramonium, hold a very high rank. You are all aware of the benefit derived from musk in the treatment of subsultus; it has been long used for this purpose, and it deserves the reputation which it holds. Turpentine is another remedy of great efficacy in convulsive affections; in epilepsy, in the convulsions of children, and in the subsultus of fever, I have frequently employed it with advantage, and can bear ample testimony to its value; but, as I said before, I think that, in the present instance, the improvement is to be attributed chiefly to the stramonium.

I am at present attending a very remarkable case of chorea along with Dr. Gordon Jackson. The patient is *seventy-two years of*

age, and the disease gradually increasing has reached the greatest possible degree of violence. The occurrence of well-marked chorea at such an advanced age, is, I believe, unprecedented. The patient is a medical man, and has been visited by Mr. Colles, Mr. Crampton, and others, who all agree as to the nature of the disease.

Speaking of turpentine puts me in mind of a curious case which came recently under my notice. You are aware that turpentine is extensively used in the treatment of tape-worm. The usual mode of administering it is to give from half an ounce to an ounce, either alone or combined with castor oil. A gentleman of my acquaintance who laboured under tape-worm, and had taken a variety of remedies, among others spirit of turpentine in the usual doses, was advised to try a very large dose of the spirit of turpentine. He took three ounces at once, and nearly killed himself; the turpentine produced the most violent irritation of the bowels, hypercatharsis, and intense excitement of the nervous system. He suffered for a long time from the effects of the dose, and to add to his misfortune, it failed of accomplishing the end for which it was taken. About half a year afterwards, while still labouring under symptoms of tape-worm, he was persuaded to try turpentine again in half dram doses twice a day. He continued this for a considerable time, until the system became, as it were, saturated with the turpentine, and then began to pass portions of tape-worm daily, until the whole came away and he recovered completely. Here, you perceive, small or alterative doses succeeded, where an enormous dose had failed.

CASES OF MUSCÆ VOLITANTES;

WITH REMARKS ON THEIR PROXIMATE
CAUSE.

By W. C. WALLACE, M.D.
Oculist, New York.

(Communicated by Dr. Forbes, of Chichester.)

CASE I.—A very intelligent gentleman, from Newark, N. J., consulted me some time ago about a network which appeared before his eyes, and impeded vision. While describing his complaint he drew with his pencil a representation of part of the vascular coat of the retina, as perfectly as if he had had a preparation of the membrane before him for a copy. I took an unusual interest

in the case from the drawing, and obtained the following account of it:—

"The appearances before my eyes are drawn as correctly as I am able; they do not appear stationary, for when I suddenly throw my eyes up they will also go up, and appear to rise above the object upon which I fix my sight; they then move slowly downward, and sink below the sight, sometimes a little on one side, and at other times exactly in the way, so as to cover a letter or figure at which I may happen to look. I can still see the object, though imperfectly, as if through thin gauze or something of the kind, which dims the sight a little. When they get on one side of the sight, and I attempt to turn my eyes to get a more perfect view of them, turning my eyes appears to turn them also, and they keep at about the same distance. When my eyes are open they do not appear so large nor so plainly as they do when I partly close my eyes. When I fix my sight upon an object, and look steadily at it for a moment or two, without moving my eyes, they will disappear; but the least motion of the eyes will bring them back again as plainly as ever. I have two or three different times noticed a kind of motion, as if caused by hundreds of small insects darting to and fro, when I looked up in the air, in strong day-light. The distance of the network appearance seems to be regulated by the distance of the objects at which I look. If I look at an object half a mile off they seem considerably farther from me than they do when I look at an object which is only two or three feet distant. The appearances are worse after a hearty dinner or loss of sleep, and they trouble me least when I feel otherwise well."

As there seemed considerable bilious derangement, I prescribed an emetic, and alterative doses of calomel. I also recommended regular cupping every two weeks, cold applications to the brow and temple, a loose neckcloth, and to avoid whatever might occasion straining. He is now much improved; the network is scarcely visible.

CASE II.—The studies of a young gentleman at Princeton College were interrupted by a network, which was always present, and impeded vision. The regular application of leeches was recommended, but they were not applied. Cold applications and aperients had no effect; mercury and iodine were

tried without benefit. The loss of blood was again urged, and the patient was immediately relieved after the application of cupping-glasses to the temple. By weekly repetition of the cupping he soon became quite well.

CASE III.—A theological student consulted me about hundreds of moving globular specks which, without any other morbid symptom, were constantly floating before his eyes, and caused much inconvenience and anxiety. At the end of a year after the first consultation he was not at all benefited, after having made use of mercury, iodine, strychnia, &c., and after having been repeatedly cupped and blistered.

CASE IV.—The writer was for upwards of a year annoyed by a floating musca, similar to a portion of the soot produced by burning turpentine. After having had to undergo a course of mercury for an attack of granular conjunctivitis, the musca entirely disappeared.

REMARKS.—The spots which, without external existence, appear before the eyes, assume a great variety of forms. To some they appear as an insect's wing, a spider with long projecting legs, a network, a branch, or an angular or straight line; to others as twisting or undulating hairs, a string of beads, a shower of opaque or transparent globules, separate or united; or they are represented as tufts of black cotton, or the black particles produced from smoke. They are more distinctly observed when the eyes are exposed to intense light, as looking long at white objects well illuminated, at flame, or at a clear sky.

Various opinions have been entertained about the nature of *muscæ volitantes*. Morgagni supposed them to arise from thickened lachrymal humour formed on the cornea. On account of their motion, Delahire thought they arose from substances floating in the aqueous humour; and to support his opinion he made the following experiment. He received upon white paper the rays of the sun through a pane of glass in which there were vesicles and filaments, and the imperfections in the glass appeared on the paper as the bodies in question on the retina*.

To ascertain if Delahire's opinion were correct, Demours opened the cor-

* Demours.

nea and evacuated the aqueous humour, as had been proposed by Leroy, without the least diminution of the appearances. He consequently concluded that the seat of the disease was the humor Morgagni, some small portions of which, without loss of transparency, had acquired a greater density and refrangibility.

As it is obvious that the light refracted by the lenses of the eye, and received upon the retina, cannot be compared to the passage of light through a pane of glass, I modified Delahire's experiment, by substituting a double convex lens which contained a number of striæ. I found that the shadows of these striæ were visible upon a screen at a certain distance from the glass, but at situations far beyond its focus. When the screen was moved toward the focus, the inverted picture was not in the least interrupted, nor were shadows produced on the picture by placing small bodies before or immediately behind the glass. Hence we may conclude that spots or filaments in the lens, or anterior or immediately posterior to it, cannot be represented on the retina.

Most people in ophthalmic practice have seen small fragments of capsule remaining in the pupil after the operation for cataract, and have found, on inquiry, that vision was not disturbed by a fixed or flying musca; nor are these symptoms produced by small ulcers on the cornea. A case occurred to Mr. Ware, in which, after the removal of a cataract, a white opaque particle, about the size of the head of a small pin, moved continually upward and downward, near the centre of the pupil. Though very perceptible to observers, it was wholly unperceived by the patient, and neither interfered with vision nor occasioned the slightest appearance of a musca volitans. I have myself operated for the removal of a fragment of capsule which floated in the pupil; and though, previous to the last operation, the vision was partially cloudy and wavering, there was no appearance that might be compared to those under consideration.

Guided in his opinion by the principles of optics, Pitcairn thought the disease arose from congestion or varicosity of some of the blood-vessels of the retina. By Willis it was attributed to insensibility of certain filaments of the optic nerve.

"The fixed musca," says Mr. Travers,

"is generally an organic affection, probably a deposit or extravasation between the choroid and retina, compressing to a certain space the papillæ of the retina, to which the musca corresponds in figure. In other instances it is independent of deranged structure, and may be presumed to be only an insensible spot of the retina."

In his memoir on the subject, published in the fifth volume of the *Medico-Chirurgical Transactions*, Mr. Ware states "that it is not easy to ascertain the proximate cause of these moats, but from the constancy in their figure, and their frequently long continuance, it seems probable that they depend upon a steady pressure upon one or more minute points of the retina, which are situated near the axis of vision, but not exactly in it. The pressure must be near this axis, because the moats always appear near the objects that are looked at; but it cannot be in the axis, because the moats do not injure or impair their natural appearance. As the pressure is not in the axis, the outline of the moats is always somewhat obscure, and the exertion that is made to bring the moats into the axis by moving the eye, gives them an apparent motion, which is sometimes upward and downward, and sometimes from side to side. That the *tunica retina* is liable to be affected by this partial pressure, may be fairly inferred from an examination of the structure of this tunic in connexion with the parts that are contiguous to it. The retina in a recent human eye has the appearance of a plain, uniform, transparent, pulpy membrane, which surrounds the vitreous humour, but is unconnected with it. On a close examination, it is discovered to be composed of two substances. One of these is an exquisitely thin membrane, on the inner side of which, in the fetal subject, many blood-vessels may be traced, and on the outer a medulla is spread, which lies in contact with the inner concave surface of the *tunica choroides*. This concave surface of the *choroides*, when well injected, has been said by Tina to have a villous appearance, produced by innumerable short flocculi, which are exquisitely minute, and indeed they are imperceptible to the naked eye. They are covered by a black mucous substance, called the *pigmentum nigrum*, which is so equally spread over the retina, that when the person is in

health it only serves to render the retina duly susceptible of the impressions made upon it by the light transmitted from external objects. When, however, a morbid sensibility is excited, like that which general debility or much anxiety is apt to occasion, the retina (which has a larger quantity of nervous medulla spread over it, in proportion to its dimensions, than any other part of the body) becomes morbidly impressed by any little points or projections that happen to be in contact with it. This morbid impression may be occasioned either by the pressure of small portions of lymph diffused irregularly between the choroid coat and retina; by some minute particle of the pigmentum nigrum, larger or more uneven than the rest; or by one or more of the minute villi of the choroides itself, and such a pressure, however it be occasioned, is sufficient, in my apprehension, to produce the image of an object similar in every respect to that of a real object so situated that light proceeding from it would have produced a similar impression upon the retina.

As it is only by a knowledge of structure that we can acquire a philosophical view of disease, we shall examine the descriptions of the retina by the authors most frequently perused.

Mr. Ware, as already quoted, says, "the retina in a recent human eye has the appearance of a plain, uniform, transparent pulpy membrane."

Sir Charles Bell, in his *Bridgewater Treatise**, which is his latest publication, says, "there is no fibrous texture in the matter of the nerve" (meaning the retina;) and again, when combating Herschel's hypothesis of vision, "it appears to me natural to suppose that if these fibres of the nerve (which, be it remembered, are also imaginary,) were moved like the cords of a musical instrument, they would be most easily continued in motion by undulations in the same time," &c.

The most modern work on the structure of the eye which I have seen, is that of Dalrymple, published in 1831. His account is as follows:—Several of the older anatomists, amongst whom we find the names of Ruysch and Briggs, assert that the retina is composed of minute fibres, evidently derived from the fibrous appearance of the optic nerve, and thence radiating in the form of

a star. Haller denies this, and attributes the appearance in question to certain plicæ or folds, into which the retina probably falls, by the evaporation or dispersion of the fluid of the vitreous body after death. It has assuredly never happened to me to observe any fibres, or any appearance that could be mistaken for fibres, in a recent human eye. Let us now appeal to nature for the correctness of these assertions.

When the inner surface of the choroid is examined with a microscope, in place of the villi of Tina and Ware we find a number of hexangular plates forming the membrane of Mondini, upon which are deposited the granules of the pigmentum nigrum.

When the convex surface of the retina is exposed under water, and scratched with a scalpel, a membrane of great delicacy may be separated, and turned over with the assistance of a camel's hair pencil. This is the coat of Jacob. When the same preparation is allowed to putrify, and the nervous matter washed away with a camel's hair pencil, the vascular membrane may be exhibited. The ramifications of the blood-vessels in this membrane resemble those of the veins of a leaf after the soft part has been eaten away by insects, and by their inter-texture they form a semi-opaque screen, on which is received the image of external objects; just as the ground of a camera obscura, or the screen of a magic lantern.

The nervous matter may be divided into two layers. By allowing an eye to macerate in alcohol, for the purpose of preventing the retina from collapsing when the anterior half of the eye is cut off, and pouring upon the retina thus exposed a watery solution of corrosive sublimate, the fibres may be seen lying beneath the vascular membrane, when they are separated from each other by a camel's hair pencil. In young animals, especially in the calf, the fibres are more easily exhibited than in those which are old. In the human eye, some of them converge round the central foramen. By pouring upon an eye exposed in the same manner an alcoholic solution of corrosive sublimate and muriate of ammonia, the fibrous coat becomes so compact and hard that it may be torn off with forceps, and a layer of globules will be brought into view. These globules are kept in place by the coat of Jacob already described.

* American edition.

The retina, then, consists of four layers—a vascular, a fibrous, a globular, and a serous.

By this exposition of the retina we may account for the various appearances of *muscæ volitantes*. I have occasionally, when entering an ordinarily lighted room, after a full meal, and exposure to a bright light, witnessed glimmerings like a network, which, from its resemblance to the vascular coat, left no doubt in my mind that the blood-vessels of the retina were visible. At other times, in the same circumstances, there was a twisted tube, or a chain of beads, as if there had been an error loci of one of the curved fibres of the retina; or there was a cloud of globules, sometimes packed together, but more frequently separated, and floating in all directions. Each globule was visible for a considerable time, and repeatedly re-occupied the same space. When clustered together, they had a great resemblance to the globules of the retina.

From the similarity of the drawing of the floating network in Case 1. to the vascular coat of the retina, I am persuaded that any person who has seen both will have no hesitation in locating the disease: and if the network, curved filaments, and globules, appear to others as they do unto me, the various *muscæ* will be ascribed to affections of the structure which they resemble.

Beer observed in some cases that the vessels of the vascular membrane had been varicose. Dr. Wardrop, in his *Morbid Anatomy of the Eye*, states that "it was observed by Sauvages, that the pulsations of the optic artery might be perceived by looking intently at a white wall, well illuminated. A kind of network, darker than the other parts of the wall, appears and vanishes alternately, with every pulsation. This change of colour in the wall he ascribed to the compression of the retina by the diastole of the artery. Richter mentions the case of a plethoric person, who, when he held his breath, and looked at a white wall, perceived a kind of network, which alternately appeared and disappeared with the diastole and systole of the arteries. Mr. George Young saw a cadet at Woolwich, who, from being obliged to wear a very tight neckcloth and collar, had his sight much impaired."

When, while the eye is directed forward at a distance, we move a lighted

candle up and down, on one side of the line of vision, a representation of the vessels of the vascular membrane shortly appears, as if displayed on a screen. The vessels are greatly magnified, on account of the portion of the retina which they occupy compared with that of an ordinary image. We may hence infer that a very minute congestion may cause a large *musca*.

It is stated by Demours that the diameter of a *musca* appears to increase in proportion as we recede from the plain in which it is examined. Such a filament as appears one-sixth of a line in diameter, and one inch long, when seen on a leaf of very white paper, at the usual focal distance, appears two lines in diameter, and more than a foot long, when we examine it by looking at a white wall, at the distance of twenty or thirty feet; and in the only case in which he mentions the subject, Mr Ware says that the magnitude of the moats depended much on the distance at which they were observed, being larger when seen far off, and smaller when near the eyes.

Can the enlargement be owing to the compression of the vitreous humour against the retina by the lens, when the eye is adjusted to distant objects? and can the diminution arise from the less degree of pressure as the lens approaches the cornea when adjusted to near objects?

It was discovered by Magendie that when the fifth nerve was cut across, the animal became blind. Sir Charles Bell discovered that each organ is supplied with two sets of nervous fibres, one for sensation and one for motion. As the papillæ of other nerves become erect when excited, it would seem that the fifth, which is a compound nerve, enables the expanded fibres of the optic nerve to be placed in a proper condition for conveying a distinct impression to the sensorium. Should there be any unusual turgescence of the vascular membrane, error loci of the filaments or globules, caused by a diminished supply from the motor nerve to the sentient fibres, effusion of lymph or varicosity of the choroid, the fibres will not be free to the action of light, but will convey false impressions; and there will be an appearance of motion, when during their erection or tension the fibres come in contact with diseased vessels, filaments, or globules.

As the image of a grain of sand, or a still smaller object, must be very minute when represented on the retina, a very

slight movement of the fibres would make the distended vessels seem to pass over a great space.

It is difficult to keep the eye on one object for a long time, but when it can be accomplished the retina soon becomes fatigued, the fibres lose their tone or tension, and the object disappears. As soon as they have rested or received an additional supply of motive nervous power, the object comes again into view, and there is an alternate disappearance and reappearance of the object as long as the experiment is continued. If, when the light is very obscure, we look intently at a feebly illuminated object, the fibres, in endeavouring to adapt themselves to the degree of light, soon become painfully affected, and the object is no longer visible. *

The connexion between the second and the fifth pair of nerves may explain why there is a halo round luminous objects during catarrhal ophthalmia, when the distended vessels press upon the filaments of the latter, which are so abundantly spread upon the conjunctiva; and why in strumous ophthalmia there is such intolerance of light when the nerves are irritated by exposure in consequence of ulceration of the anterior membrane.

I have noticed that pressure on one part of the retina conveys an opposite impression to the brain. If I shut my eyes and press the retina of one of them with a finger on the outside, the circle of light which is thus produced will appear as if proceeding from the inside. If I press above, the circle will seem below; and if I carry the finger completely round the eye, the light will always be opposite to the finger. Hence we may conclude that the upper part of the retina is diseased if the spot is seen below, and *vice versa*. We may also thus account for erect vision, although the image of objects is inverted.

ON THE NATURE OF VACCINATION.

To the Editor of the Medical Gazette.

SIR,

I HAVE read with much interest and satisfaction, in your journal for September 15th, Mr. Estlin's letter on the subject of Vaccine Virus obtained fresh from the Cow. Of the importance of

obtaining from its original source the means of propagating the vaccine disease, most professional men have been for some time well assured, and the difficulty of effecting this object has appeared somewhat extraordinary. In Jenner's time did any such difficulty exist? and if not, as I believe, whence, I would ask, has it since taken place? In this question is, perhaps, involved another of still greater interest. Whence did the disease originate in the cow? It is well known that Jenner supposed it to arise from inoculation with the matter from the heel of the horse affected with grease. But are there not still greasy horses? And if from this source so frequently formerly, why so rarely in later times? This fact would lead us to inquire, whether some other cause was not in operation to produce the disease in the cow, which, since Jenner's discovery, has been of less frequent occurrence? and whether that discovery is not itself very closely connected with the less frequent occurrence of the vaccine pustule on the teats of the cow? If it should be ascertained, as appears very probable, that the cow was, in the first place, infected by the hauds of a milker who had lately been affected with small-pox, not only would a very interesting and important fact in physiology be brought to light, but a very valuable practical fact also, inasmuch as it would give us the power of obtaining at will, during the prevalence of small-pox, a fresh supply of mitigated virus, by passing the disease through the system of the cow, which might be done in any part of the world.

The analogy between the vaccine disease and small-pox, the extraordinary protective power of the former from the infecting influence of the latter, and the rare occurrence of it in the cow itself since the small-pox has been rendered less frequent by the practice of vaccination, have long induced me to believe that cowpox was really a form of small-pox mitigated by passing through the system of another animal.

Should Mr. Estlin have opportunity of verifying or disproving this supposition, I am sure that he will render an essential service to human nature by availing himself of them, and will settle a physiological question of much interest. He will perhaps permit me, therefore, to invite his particular attention to the solution of it, and to assure him that, what-

* Sir D. Brewster.

ever may be the result, he will greatly oblige the writer of this note.

I remain, sir,
Your obedient servant,
T. M. GREENHOW.

Newcastle-upon-Tyne,
October 7th, 1838.

ON THE NEW VACCINE VIRUS.

MR. ESTLIN'S SECOND LETTER.

To the Editor of the Medical Gazette.

SIR,

THE letters I have received from various professional men, in consequence of my communication inserted in the GAZETTE of the 15th of September, convince me that my own anxiety to procure a supply of fresh vaccine virus from the cow, has not led me to overrate the interest of many of my brethren in the same object. The favourable light in which they are pleased to view the very moderate exertions I have had to make, cannot but be gratifying to me; and I feel it due to them to report the result of the farther experience I have had of the new lymph.

In my former letter I stated, that the lymph brought to Bristol from the Gloucestershire farm, and successfully employed in inoculation, was removed from the cow only two degrees, having passed through one of the milkers, and the child Jane, inoculated from her. I have now (October 10) under vaccination the sixth set of Bristol patients.

A very few only have been unsusceptible of the disease, and there has, upon the whole, been much uniformity in those characters which appear to me to distinguish the new lymph from that commonly employed. I refer to a larger, and longer-continued areola, more constitutional disturbance, and a much deeper indentation left on the arm. The depth in the cellular membrane to which the vesicle extends, is a marked feature in the new lymph. In some cases under my care, when during the third week the scab has been rubbed off, there have been deep, though not wide, circular cavities, that would have contained the whole of a pea not of the smallest size. The scab, if not rubbed, has seldom come away before the fourth week.

The period of teething being that during which children are most commonly brought for vaccination, it is not

always easy to discriminate between the consequences of the inoculation, and the irritation from the teeth; and the mothers certainly often attribute to the cow-pox, symptoms which dentition produces; but I am satisfied I have in some instances seen vomiting occur, at intervals, during the first week, in consequence of the vaccination. One child, vaccinated in four places, very near to the shoulder, had the vesicles so much disturbed by the dress, as to present rather deep circular ulcers on the fifth day: much inflammation accompanied the progress of the vesicles for about a fortnight, and two abscesses have formed in the axilla, one of them five weeks after the inoculation, and even after the cicatrization of the vaccinated spot. A scrofulous child whom I vaccinated on one arm with lymph taken on the eighth day from the other arm, had an abscess produced on the spot of the second inoculation, which I was obliged to open: it contained thick pus, had been twelve days in forming, and showed no trace of the inoculation. A similar abscess had formed under the child's chin previously to his being vaccinated. One or two more have had an abscess in the axilla.

More general cutaneous affection has been produced by this lymph than I believe to be often seen after the employment of the common matter. In some children a slight vesicular eruption has appeared during the first or second week; in others, rashes have come on at various periods, even after the third week. Though the parents have occasionally expressed uneasiness at these unusual cutaneous accompaniments, they have generally been pleased with the severity of the complaint, although so much greater than they have been accustomed to see, believing that more complete security against small-pox was thus ensured. I mention all these circumstances without any regard to the impression they may convey respecting the value of the new virus; my only desire is, that others may have the same means of forming an opinion that I have, in order that its merits or demerits may be investigated. I must consider the evidence of its being even of equal value with the lymph previously in use, as incomplete, until it has been tested by small-pox inoculation. In consequence of the active inflammatory action which some children have had from three and four insertions of lymph, I

now, for the most part, confine myself to two; and whenever the infection has taken in only one place, there the least local inconvenience has followed. My practice is, to insert the lymph by means of scratches made within a small space. Those vaccinations which have been least satisfactory were such as have been performed upon sickly children, or those that had eruptions.

The re-vaccinations I have practised tend to shew the energy of the new virus. The following are the results in twenty cases:—In four no effect was produced beyond a little redness, or a small pimple, lasting two or three days. In eight persons, whose ages varied from three to sixteen years, there occurred irregular vesicles, with more or less inflammation beginning on the third or fourth day, and continuing for eight or ten days. In four others, there was rather severe inflammation, producing much uneasiness in the part, and pain in the axillary glands; (in one of them two sloughs formed where the virus had been inserted; the lady who was the subject of this vaccination was confined to the house for some days, and the ulcers had not healed at the end of five weeks.) In two of the cases, ladies who had been vaccinated twenty and thirty years ago, flat and tolerably circular vesicles were formed, with a moderate areola, but the areola came on early, and continued for many days. These two cases, however, exhibited the nearest approach of any to a regular vaccine vesicle, but with neither should I have been sufficiently satisfied to have taken lymph for use, had they existed in persons not previously vaccinated. In the two remaining cases, there were small vesicles, and slight areolae, for four or five days. In none, however, of these twenty instances did the vaccination run the same course that it has observed in children who had not previously been subjected to cow-pox infection. The cicatrices of the original vaccination in these individuals varied: some were well marked, others very faint, but there seemed no relation between the progress of the lymph and the extent of the original scar.

The new virus is now extensively employed in this city. Messrs. Wilson, Carpenter, Goodeve, Swayne, and several other surgeons of Bristol, are vaccinating with it, and are fully satisfied, as far as appearances go, of its superiority to the matter commonly in use.

Dr. Gregory, of the Small-Pox Hospital, in a letter (the words of which I am sure he will allow me to quote), after detailing the failure of a former trial, says, "The Bristol lymph is of very excellent quality. Had I had any doubt of the good qualities of the lymph I have now in use, I would forthwith have adopted it (the Bristol lymph), and I am sure I could fully have relied on it."

Dr. Gregory was unable to continue the stock from accidental circumstances; but had he been able to do so, he must soon have relinquished it, from its not being in his power to keep up two different kinds of lymph during the winter.

It is too soon, probably, for me to become acquainted with the result of its use in other quarters; but as I have sent a supply to another medical gentleman in London, as well as to practitioners in Dublin, York, Bangor, Retford, Oxford, Bath, Falmouth Harbour, Gloucester, Swansea, Malvern, and many other places, and as the burthen of almost every letter I have received (with the exception of Dr. Gregory's) is, dissatisfaction with the present stock of lymph, and unavailing efforts to procure a fresh supply from its original source, I have no doubt of its undergoing a sufficient trial.

One gentleman informs me that he has repeatedly inoculated cows with vaccine virus from the human subject without success. A more fortunate result attended a similar experiment in this neighbourhood. A friend having given me permission to vaccinate one of his cows, the experiment was conducted, during my unavoidable absence, by Mr. Wilson. Vesicles were produced on the cow's teat, running their course in about fourteen days. Children were inoculated with the lymph they furnished, and regular vesicles were reproduced upon their arms; but the lymph, after having thus passed through the cow, produced vesicles in no obvious character differing from those that it gave rise to before it was so treated; and after two or three weeks the stock was accidentally dropped.

The inquiries and correspondence I have been engaged in for the last two months have led me to the adoption of the following conclusions, though, I hope, with no undue confidence in their soundness:—

That the vaccine disease in the cow is not of very common occurrence, and

that it is more prevalent in the south-west counties of England than in others; and that matter taken from the cow, and inserted into the human subject, in the ordinary method with a lancet, seldom reproduces the disease; and that it is the greater exposure of the milker's hands to the morbid poison, sometimes probably with cutaneous abrasions, that renders them more liable to receive the infection than those who are comparatively slightly inoculated with it.

I still hope, with the aid of those friends who are also using the new lymph, to be able to furnish with it any medical gentleman connected with a public institution for gratuitous vaccination, who is anxious to give it a trial; but I would particularly urge, in order to secure a satisfactory beginning, that a healthy child be selected for vaccination, and one that is free from every kind of eruption.—I am, sir,

Your obedient servant,

J. B. ESTLIN.

Bristol, October 10th, 1838.

P.S.—Oct. 11.—After forwarding my letter of yesterday's date, I received from Mr. J. Soden, of Bath, the following report addressed to him by Mr. Gore, surgeon, of that city:—"I find the whole number vaccinated by myself or by deputy since Sept. 15th, from Mr. Estlin's stock of matter, to be 14." "It appears to be of a very satisfactory kind; as regular in its progress as that we have been in the habit of using, but more severe as regards the extent and degree of the surrounding areola. I have watched it in three successive removes from the stock received from Mr. Estlin, and have not observed any modification or diminution of its intensity." "I am still keeping it up."

[The above interesting communication came to hand too late for it to be inserted in our last number, as the author intended.—ED. GAZ.]

ON THE SECALE CORNUTUM.

To the Editor of the Medical Gazette.

SIR,

I SHALL feel obliged by your permitting me to make a few remarks in reply to the observations of Dr. Cory, which ap-

peared in the GAZETTE of Sept. 1, on a short paper of mine, intended to illustrate the properties of secale cornutum. I have been absent from home from that period until lately, which I trust will sufficiently acquit me of any want of courtesy to your respectable correspondent. I would also observe, that I feel much honoured by the complimentary tone in which the Doctor has remarked on my paper; and I assure you, sir, it is no small gratification to me to find that there is so great a correspondence of opinion on the subject between myself and so able a practitioner.

I endeavoured to explain in my first paper the reasons which induced me to communicate them to the profession. I had observed repeatedly, that errors were being committed by men of considerable reputation in the administration of this drug; whilst the junior members of the profession seemed quite undecided as to its real merits, and the proper indications for its exhibition. The general practitioner, engaged almost constantly, can spare but little time for reading, and I conceived that a condensed statement of its principal characters would be calculated to remedy some of these defects. The papers have been drawn up perhaps without sufficient attention to style and arrangement, &c., but the facts have been selected from a very considerable number, the results of years of careful and assiduous observation. A sense of duty has been my sole motive for bringing them before the profession, in the hope that they might be useful.

Having premised thus much, I shall proceed to notice the objections of your correspondent; and it is not without regret that I find him endeavouring, almost *in limine*, to give a meaning to my words which I think they do not convey. The Doctor asks "for the high authority which sanctions the exhibition of secale in cases of threatened abortion about the fourth month, and with a rigid and contracted os uteri." A reference to my paper, sir, will shew that the rigidity of the os uteri is not mentioned as existing previously, but subsequently to the administration of the ergot; in fact, that it is stated as one of the effects of the administration of that drug at an improper period. My words in describing the state of the os uteri are, "the os uteri was found dilated so as to admit

the point of the finger." Surely there is nothing in this about a rigid and contracted os uteri. This is scarcely fair on the part of your correspondent. The high authority to which I adverted was the learned author of the Dictionary of Practical Medicine; he says, "When the embryo only is expelled, the appendages being still retained, or when the hæmorrhage is great, the entire ovum still remaining in the uterus, the ergot of rye will prove of inestimable service."—(See Copland's Dictionary, art. *Abortion*, 37.)

The doctor seems also to think in this instance "abortion might have been prevented, at any rate that it ought to have been attempted" I am sorry to add that the experience of your able correspondent does not at all accord with mine on this point. I have invariably found, in cases of threatened abortion, that when the hæmorrhage has increased, accompanied with pains, uterine contractions, and dilatation of the os uteri, abortion has taken place, and that any attempt to prevent it has proved unavailing. And I think I do not stand alone here. The author of the admirable work above mentioned says, "The foregoing plan will often succeed in preserving the infant, unless the discharge continues, or becomes more copious, the uterine pains, with the other symptoms of commencing abortion, still persist, or increase, and the woman be far advanced in pregnancy, when little advantage will be obtained, particularly if the orifice of the womb dilate: when this is the case, attempts at preservation will entirely fail." Professor Burns, speaking on this point (see his Principles of Midwifery, art. *Abortion*), says, I know that we have been told of instances where contraction, after beginning, stopped for several weeks. The os uteri may be prematurely developed—it may be open for some weeks without pain, but no man will say that in this case labour or uterine contraction has begun." A little farther he adds—"It (uterine action) may, like other muscular actions, be suspended by anodynes, or artificial treatment, but it never has, and never can, be stopped, otherwise than by the expulsion of the ovum, when a new train of actions commences. Whenever, then, at any period of pregnancy, we have paroxysms of pain in the back, and region of the uterus, more

especially if these be attended with a feeling of weight in that region, tenesmus, micturition, descent of the uterus in the pelvis, and opening of the os uteri, we may be sure that expulsion, though retarded, will soon take place."—P. 259, edit. 5th. The opinions of these able men sufficiently shew that in the above case any further attempts at prevention must have ended in disappointment. To the objections of Dr. Cory to what he calls a fanciful hypothesis, I can only reply by briefly stating the steps by which I arrived at that opinion. I would just remark, that it has been thrown out merely as a suggestion, not as a theory. I am strongly attached to the great principles of the illustrious Bacon, and should feel that I was treading on dangerous ground if I followed any other course in the pursuit of sound knowledge. About seven years ago I was attending a case in which the ergot had been administered during the early stages of labour, and I was surprised to find the abdominal muscles were contracting powerfully, while the os uteri and all the parts of the cervix which I could reach seemed unaffected. Repeated examinations were made, and after about twenty minutes the uterus began to take on an irregular and powerful action. This case first induced me to watch the matter, and in a very large number of cases I have observed the same order of events: first, contraction of the abdominal muscles; secondly, uterine effort. These effects are most obvious if the secale be given at an early stage, when I think any careful accurate observer will be satisfied of the precedence of action in the abdominal muscles, and the succession of uterine action. When the expulsive efforts have arisen in the course of labour—that is, when the os uteri is dilated—this order of things is not so appreciable. As far as I am aware, sir, there is nothing in this contrary to the Baconian philosophy.

The next point animadverted upon by your able and intelligent correspondent is the error which I have endeavoured to point out of administering the ergot at too early a period; and here I regret to find that the Doctor has again fallen into the error of supposing that I have described the os uteri as in a rigid state; whereas I have endeavoured to point it out, as a consequence of its improper exhibition. That this particular

error is not a solitary instance, occurring in my own sphere of observation, Dr. C. will find abundant proofs in the communication of Mr. J. B. Clutterbuck (see GAZETTE of Sept. 8), who says "he has given it in his last thirty cases, where the orifice of the uterus had not been dilated to more than the circumference of a shilling." Besides, I can assure Dr. Cory the gentleman to whom I have referred in my paper is an intelligent practitioner, and esteemed such in his own neighbourhood. I hope I have satisfactorily replied to the objections of your correspondent. I beg to apologize for having trespassed so much on the columns of your esteemed journal.

I am, sir,

Your obedient servant,

JOHN ARMSTRONG.

Gravesend, Sept. 28, 1838.

P.S.—Your correspondent, Mr. Clutterbuck, errs in stating that Dr. Cory has recommended coffee as the best vehicle. Dr. C. has recommended tea. If Mr. Clutterbuck will try the coffee as recommended by me, but not too early in the labour, he will find it by far the best vehicle.

REMARKABLE CASE

OF

ECCENTRIC ATROPHY OF THE BONES.

BY JOHN THURNAM,

Resident-Surgeon to the Retreat, York.

Chronic Rheumatism (?) followed by Ankylosis of all the principal joints—Death in three years from Pleurisy—Acute and Chronic Empyema—Eccentric Atrophy of the Skeleton generally to a remarkable extent.

LOUISA TATUM, aged 19, unmarried, the daughter of a country labourer, was admitted into the Westminster Hospital, Sept. 5th, 1837, under the care of Dr. Roe.

She was completely crippled and bed-ridden, from rigidity of all the principal joints; lying constantly in one position on the back, with the knees separated as far as possible from each other; the thighs flexed slightly on the abdomen; the legs almost forming right angles with the thighs, and the feet everted.

The upper extremities were perma-

nently extended, from the ankylosed condition of the elbows and shoulders, but she retained the use of many of her fingers, and fed herself with the assistance of a fork mounted on a handle of about 2½ feet in length. The joints generally, but especially the knees, were pale and glabrous, and appeared enlarged; but this was probably owing, at least in part, to the wasted condition of the muscles and other soft parts. Great pain was excited by pressure, or attempts at extension of the joints, but at other times she did not suffer. There was a chronic eczematous eruption over many parts of the body, especially about the knees and feet, which first shewed itself about six months since, soon after the first appearance of the catamenia, at which time an improvement in the general health was noticed.

She stated that her illness commenced about three years since, after getting wet in the feet, in the form of a rheumatic affection of the joints; there being pain and swelling of the left foot and both the knees, for which she had little or no medical treatment instituted by the parochial surgeon to whom she applied. She was confined to the house for two months, after which she got out again for twelve months, "hobbling along with a stick, in great misery." The disease, however, increased, and gradually extended all over the body, in the shape of stiffness of the joints, so that about two years ago she was obliged altogether to take to her bed. From the indigent condition of her parents, she had been living in a state of comparative distress, and had for some time been sleeping in a room with a damp stone floor.

The remedial measures employed were of course almost entirely palliative, and do not require to be detailed, as the condition of the joints remained unaffected. She had a slight cough and rather impaired breathing when she came in, and the general idea was that there were tubercles in the lungs, but her circumstances precluded this being satisfactorily ascertained by a physical examination. After she had been in the hospital about two months and a half, her health began more evidently to decline, and the pulmonary symptoms to be more urgent. The cough and expectoration increased, and were accompanied by hectic paroxysms, and profuse unpleasant and acid perspirations.

About the third week in December she further complained of palpitation and pain in the left side of the chest about the region of the heart, the pain being increased by pressure. Upon uncovering the chest the increased action of the heart was visible to the eye, and upon applying the stethoscope the impulse was found to be increased; the sounds, especially the second, louder than usual, but scarcely heard beyond the præcordial region. The pulse, compared with the heart's impulse, was feeble. The upper and anterior regions only of the chest could be explored with the stethoscope; and in these situations the respiratory murmur was defective and bronchial, and obscured by sibilant and sonorous wheezes; there was also bronchophony (?). From this examination I was confirmed in the idea that there were tubercles in the lungs in the stage of softening, and that there probably was also subacute pericarditis; but the diagnosis was of course only problematical. She gradually sank, and died December 31st, 1837.

Dissection, 36 hours after death.—The body generally was much emaciated, but this appeared to be dependent upon atrophy of the muscular structures, as there was an abundance of subcutaneous fat. The brain was healthy.

Thorax.—The right lung was compressed by an empyema evidently of old standing, and was not of more than a fifth of its healthy bulk; its tissue was very dense, of a grey colour, and contained a few crude tubercles. The costal pleura, with the false membranes lining it, had attained to a great thickness, and was of a semi-cartilaginous texture, and studded with tubercular granulations. The left pleura was also the seat of effusion to a less extent, from a recent hæmorrhagic pleuritis. The left lung contained no tubercles. The pericardium contained about six ounces of serum, but there were no traces of pericarditis, and the heart was healthy.

Abdomen.—The abdominal and pelvic viscera were all healthy; and the cavity of the pelvis had its normal dimensions.

Ossæous system.—Several of the principal joints on both sides of the body were examined, and were uniformly found to be the seat of fibro-cartilaginous anchylosis, passing into the osseous form. The patellæ were united to the femora by a complete bony

medium. The tendons and ligaments around the joints appeared quite healthy. The remains of the synovial membrane of the knee-joints were thought to be rather more vascular than usual. The calvaria was the only portion of the osseous system examined that retained its healthy characters. Nearly all the bones of one upper and of both lower extremities, and the bodies of the vertebræ, were examined, and were found to be the seat of extraordinary eccentric atrophy. The external dimensions of the bones appeared quite normal, but their walls were reduced to an amazing degree of tenuity; those of the tibiæ and femora in no places appearing to exceed half a line in thickness; in many places, particularly about the heads of the bones, being scarcely so thick as writing paper, and here and there being altogether absorbed, producing a perforated appearance. The cavities of the bones were filled with semifluid marrow, suspended in a delicate but reddish medullary membrane. The cancellated structure was very delicate in the spongy bones, and in the extremities of the long bones: there were scarcely any remains of it in the shafts of the latter, so that after maceration the tibia had considerable resemblance to the bone of some large bird, only that its internal cavity was larger, and its walls thinner. The left tibia, after maceration and drying, only weighed one ounce and three-eighths, troy. The periosteum was detached from the bones more readily than usual. The chemical constitution of the bones has not been examined, but it would appear to have been healthy, as, *taking into consideration their delicate texture*, the bones did not present any abnormal degree of brittleness on the one hand or of softness on the other. A specimen of the bones has been deposited in the Museum of the Royal College of Surgeons, London.

OBSERVATIONS.—The last remark in the account of the preceding case leads me to observe, that since the publication of the interesting researches of M. Proesch, in Germany, and more particularly of those of Mr. B. Curling in this country, the terms *fragilitas ossium* and *mollities ossium*, with the various synonyms of the latter, osteo-malacia, mala-costeori, osteo-sarcosis, &c. can no longer be regarded as representing two distinct diseases, nor as constituting ap-

propriate nosographic epithets. The researches, in fact, of these authors would lead us to the conclusion that softening and fragility are both nothing more than symptoms which may occur in the course of several distinct diseases of the osseous system, and that they are each of them more particularly observed in different stages of the remarkable lesion which characterizes the disease usually called *mollities ossium*, and to which Mr. B. Curling has very appropriately applied the name of *eccentric atrophy of bones*. This has been apparently placed in a very correct point of view by M. Proesch*, who observes, that "although the bones are much more easily broken than healthy ones, this fragility is attributable rather to the extreme attenuation of their compact shells or outer laminae, than to any excess in the proportion of their inorganic to their organic component parts, or than to any softening (as the term *osteomalacia* implies) of the general osseous texture; 'ils se rompent plutôt qu'ils ne se cassent.'"

The general history of the case of Tatum would seem to shew that, in the first instance, it was one of rheumatism, which, its treatment having been neglected, and the disease having been allowed to run on into a chronic and intractable form, had terminated in ankylosis. The complete state of inaction into which the osseous system, in common with the body generally, was, in consequence of the rigidity of the joints, necessarily placed, would of course have favoured any tendency to the production of atrophy of the bones that might have previously existed; or not improbably would, even of itself, have been sufficient to lead to its development.

I am aware that as in almost, if not in quite, all the cases of this lesion that have been recorded, the disease has been ushered in by pains in the limbs, it may perhaps be questioned how far those which were experienced in the commencement of the case of Tatum should be regarded as of a rheumatic character. I think, however, that the character, causes, and course of the affection, in the first instance, are favourable to the conclusion of this question in the affirmative. The case is, at all events,

peculiarly interesting, from its presenting us with a generally ankylosed condition of the joints; being apparently, with one exception*, the only one on record, in which such a complication existed.

The view which I have taken of the mode of development of the disease in this instance, would appear to be supported by a well detailed case, reported by J. C. Planck†, which is stated to have had its origin in an attack of "acute rheumatic fever, which had passed into chronic rheumatism." In this case, however, although the patient survived ten years, no ankylosis had taken place.

P.S.—The foregoing case I forwarded to, and placed at the disposal of my highly respected friend, Mr. T. B. Curling, whose investigations on this disease have contributed so much to its elucidation. Finding, however, that he was not likely to make any further remarks on this subject at present, I am unwilling longer to defer the publication of a case which I incline to think one of much interest.

With Mr. Curling's permission, I here add the following note, which I received from him when he returned me the MS. In this it will be seen that he differs from me as to the *probable* cause and mode of origin of the lesion, and inclines, I believe, to the idea of its being a lesion dependent upon a constitutional disease, *sui generis*, rather than one which may result from different pathological conditions of the system—a rheumatic one among the number. The latter view is the one which I am inclined to adopt, whilst fully admitting that this is a question which, at present, we are unable satisfactorily to determine.

I may observe, that Mr. Curling has slightly misconstrued the degree in which I have represented "the state of inaction" as a cause of the lesion, when he alludes to my considering it as sufficient to account for this disease of the bones." It will be seen that, in *this* case, I do not attribute to the circum-

* *Commentatio de Osteo-malacia*. Heidelberg, 1835. See also *Med.-Chir. Rev.* vol. xxv. p. 496; 1836.

* The 16th case in Mr. B. Curling's paper, *Med.-Chir. Trans.*, vol. 20, p. 360.—M. Saillant's case. *Hist. de la Soc. Roy. de Méd.* In this case only a few of the joints were found ankylosed.

stance alluded to more than an auxiliary causative influence.

Retreat, York, October 4, 1838.

The following is the letter from Mr. Curling:—

MY DEAR SIR,—I return, with many thanks, your interesting case of Eccentric Atrophy of Bone. I cannot quite agree with you in opinion that the state of inaction was sufficient to account for this disease of the bones, as in all cases of atrophy from diminished activity I have always found the external dimensions smaller than in the healthy state, and the entire bones of diminished size, which does not appear to be the case in this instance. There is no example, I believe, on record, of the disease occurring at so early an age as in the case of Tatum. It has been calculated that rheumatism is more prevalent among men than women, whereas our present experience of eccentric atrophy of bones makes by far the larger proportion of cases in those of females. How does this affect your view of its rheumatic origin? There are so few well-described cases of the disease on record, that I hope to see yours in print.

Very truly yours,

T. B. CURLING.

1, Mount Place, London Hospital,
July 13, 1838.

DILATATION OF URETHRA—SIMPLE MODE OF EFFECTING.

To the Editor of the Medical Gazette.

SIR,

THE brevity of this communication may perhaps induce you to give it a place, if you think the mode of overcoming a difficulty which it describes, of sufficient importance.

Being called to a little boy, about seven years of age, labouring under suppression of urine, I found him in a state of agony and spasm really alarming.

On examination I perceived in the urethra, close to the pubes, a stone about the size of a small French bean. The efforts to force it onwards were most violent, and likely to lead to rupture of the urethra, if not soon relieved.

I thought of letting out the stone by an incision, but determined to try first what could be done by dilatation.

It was clear that a bougie of sufficient

size could not penetrate near enough to the stone to give relief.

I therefore inserted the point of a syringe of such a size as could be commanded with one hand, and forced warm water into the anterior portion of the urethra with a steady pressure, and had the satisfaction of producing, in about ten or fifteen minutes, sufficient dilatation to allow the passage of the stone.

Your obedient servant,

A. L. WIGAN.

Montpellier Terrace, Brighton,
4th Oct. 1838.

GANGRENA ORIS.

To the Editor of the Medical Gazette.

SIR,

IF the following hastily-sketched particulars of a case of gangrena oris, (rendered curious by the rapidity of its progress, and also by the fact of the sister of the patient having been similarly attacked after a case of fever, and as hastily carried off,) should appear to you of sufficient interest to merit a place in your columns, its insertion will oblige

Yours, &c.

W. H. B.,
Surgeon.

Henry Markham, æt. $3\frac{1}{2}$ years, a fleshy, healthy child, of poor but decent parents, was brought to me about three weeks since, labouring under an attack of typhus fever. The symptoms, which from the first were mild, at the end of ten days had totally disappeared, and no further attendance being considered necessary, I neither saw nor heard any thing more of the child till the evening of Wednesday last, when the mother, somewhat alarmed, begged that I would call and see the child as soon as possible, as she feared that a disease similar to what deprived her of one of her other children not many months since had attacked him. In compliance with her wishes, I attended in a little time. The face had now become the diseased part, and was so much swelled that the patient could scarcely see out of his left eye. On examining the inside of the mouth, my surprise was excited at finding the gum bordering the molar teeth in a state of gangrene. The mother informed me that the child had complained of no uneasiness in the face; that that morning,

on waking, he had taken a tooth out of his mouth, which he found lying loosely therein; and that the first symptom which attracted her attention was a swelling, about the size of a pigeon's egg, on the exterior of the cheek.

The usual remedies, viz. acid gargles, with myrrh, and the internal exhibition of mineral acids with bark, were my prescriptions, and persevered in for a short time, but without making the least impression upon the disease, which went on most rapidly, and in a few hours disfigured the face most frightfully. At my recommendation, on the day after I had seen it, the child was taken to the London Hospital, and there examined by Mr. Scott and Mr. Hamilton, who wished it to be left in the hospital, at the same time holding out no hope of recovery, which indeed the mother never anticipated: the gangrena oris which terminated the existence of her other child having been ushered in by a slight case of fever, and having extended by similar rapid strides, a similar doom she rightly conjectured would be ere long the fate of this. The gentlemen, however, prescribed; but before the child reached home a black spot about the size of a sixpence had made its appearance on the cheek externally, and the right side had now become nearly as much affected as the left. It was found impossible to get any thing into the stomach. A mortified spot shortly appeared on the exterior of the right cheek; the two spots rapidly increased; in a short time from the ear to the chin was a mass of gangrene; the eyes were now completely blocked up; and in a few hours were closed in death.

It is proper to mention that in the treatment of the fever salines and diaphoretics were the only medicines used, and that not a particle of mercury was administered in any form.

CASE OF FITS WITH VERY SLOW PULSE.

To the Editor of the Medical Gazette.

SIR,

I FORWARD to you the report of a case which came under my care, with the view which I have taken of it. You will perceive it presented very singular symptoms; the pulse, for instance, being as low as 16 in the minute. It must be,

I think, regarded as interesting, and if you think it worthy of insertion in your valuable and widely circulated journal, you will oblige

Your obedient servant,

JOHN R. GIBSON.

115, Holborn Hill.
Sept. 25, 1838.

Mr. W., æt. 70, although not appearing so old, whose habits have been always temperate and regular, has led an active life, and enjoyed a good state of health, with the exception of fits. The sudden and unexpected manner in which he has been attacked for the last eight years, and the severe injuries he has sometimes sustained, have rendered it necessary he should go but little from home; and whenever he has done so, for the last seven years, he has always ridden in some sort of carriage. About twenty years ago he had a slight fit, which did not return for a long period; but he has been subject to what he termed a swimming in the head, which would make its attack suddenly. His extremities of late have been always very cold. For the last eight years the return of the fits has been much more frequent; and although they would occur at periods devoid of any peculiarity, yet they have been observed to return more frequently on occasions of excitement. The attacks have been always uncertain, both as to number and frequency; there being sometimes one fit only, at others, two or three; but when one occurred singly it was always more severe than when two or three came together. The interval between the attacks has also been irregular; sometimes a month, at other times a longer or shorter period intervening; and, until the last attack, he had no true fit for a period of six months, so far as the knowledge of his friends extends; but before this period they had been much more frequent than usual. It is, however, right to observe, that he was so tenacious of secrecy regarding these fits, that if one part only of his family were aware of his having had an attack, he would request the other part might not be informed of it. It is, therefore, fair to infer that he might have had many slight attacks without the knowledge of any one.

On Sunday, July 29th, he had a slight attack, which he did not mention to any one until the Wednesday following, when he had a return. The fit, it ap-

pears, had not been severe; but he felt different to what he had ever previously felt, which gave him some alarm, and from this time he pertinaciously entertained the idea he should not recover. When I saw him (11 p.m. on the same day) his surface was bedewed with a cold and profuse perspiration; his bowels had not been relieved that day; he had taken salmon for dinner, and had vomited, with him a very uncommon occurrence; there was a sense of uneasiness about the stomach, principally nausea; there was no tenderness on pressure at any part of the abdomen, but there seemed a degree of fulness; his tongue was dry and rather red; his pulse was but 22 in the minute, full and firm; there was no pain or uneasiness about the head, and his mind was quite correct, although he appeared somewhat depressed. He had no fit while I was with him. Upon inquiring of him whether he felt any sensation when the fit came on, he said, "none but a whizzing, which seems to fly up to my head." I directed hot bottles to be applied to his feet, and the following medicine—

R Hyd. Chlorid. gr. iij.; Ext. Col. C. gr. vj.; Ext. Hyosey. gr. iij. Misce fiat pilulæ iij. s. s.

R Sp. Ammon. Aromat. ʒj.; Tr. Card. C. ʒj.; Sodæ Sesquicarb. ʒj.; Mist. Camphoræ ʒvj. M fiat Mist. Sumat ¼ partem st. et 2nda quaque horâ.

August 2d.—He had a very severe fit shortly after I left last night, and many during the night, with very little sleep; his bowels have been freely moved, and the evacuations are dark and offensive. Pulse 17 in the minute, but not of the steady firm character of last night, there being sometimes a firm, at others a faltering beat, and no constant interval between each; surface still in the same cold clammy state; tongue not altered. Upon listening to the heart I could not detect the proper sounds, but merely felt the impulse, which, in accordance with the character of the pulse, was sometimes decided and forcible, at others feeble.

To continue the mixture, but increase the dose of Sp. Am. Arom. To take Hyd. Chlorid. gr. ss.; Ext. Col. C. gr. ij.; Ex. Hyosey. gr. j. in a pill, every four hours.

4 p.m.—Had many fits during the day, and was suffering from them while

I was with him, which were as follows:—If slight only, the face became pallid, the respiration rather laboured and quicker than natural; no pulse, but directly the heart acted the pallor rapidly gave way to a blush, and all was as before. If severe, the pallor increased; the expression became ghastly; the eyes turned up; involuntary twitchings; the respiration quick and laboured, with the alæ of the nose violently drawn in at each inspiration, producing a peculiar noise; the surface cold; perfect loss of sensation, volition, &c., and sometimes an involuntary discharge of faeces and urine. The heart was not acting; and I observed, for more than half a minute, no stroke whatever of the heart could be detected. If a feeble action of the heart only took place, such as could scarcely be felt at the wrist, the symptoms would continue; but directly a decided contraction occurred the face would immediately be changed from pallor to redness; then a suspension to the breathing, in which the hand would be raised to the throat; an apparent state of strangulation existed for a moment; sensibility immediately returned: the pulse would then beat steadily for about five strokes, at the rate of 60 in a minute; and he would always, without exception, conceive he had been asleep. At this visit I again examined the heart, and thought I heard the proper sounds, although indistinctly. I then ordered a large mustard cataplasm, mixed with vinegar and mustard, to be placed over the region of the heart and epigastrium, and when it had remained on as long as it could be borne, a blister was to be applied upon the same part. My reason for ordering both these was, that when a blister had been previously applied, no vesication had been produced. I also bled him to about eight ounces. The fits continued during the bleeding. The blood did not flow freely, and it was of a very dark colour; and during the first stage of the fits it was difficult to get any blood.

Omit. Pilulæ.

9 p.m.—The fits have continued at intervals; the pulse about the same.

Cataplasmata sinapis pedibus; Emplast. Lyttæ neechæ.

R Sp. Ammon. Aromat. ʒij.; Mist. Assafetid. ʒvj. M. Fiat Mist. ejus sumat. ¼ partem 3tia quaque horâ.

Aug. 3rd, 10 A.M.—He had a strong desire, after our visit, for some beer, which was given him, after which he went to sleep; passed a pretty comfortable night, with the exception of the irritation which the blister at the nape of the neck produced, and had no fit till nine this morning, which has been repeated.

The surface is not so cold as it was yesterday, but the other symptoms are much the same.

4 P.M.—The fits have returned very frequently during the day; pulse 17, irregular and intermitting.

R Sp. Ammon. foetid. ʒij.; Liq. Volat. C. C. ʒij.; Aquæ Pulegii ʒvij. M. Sumat. coch. i. minim. ex aquâ 6ta. vel 4ta. quâque parte horæ.

9 P.M.—Continued much the same since my last visit. At this time Dr. Roots accompanied me, and made a very careful examination of the case, as he is always known to do, but could not detect the natural sounds of the heart. The pulse was 16 in the minute; but some of the beats were so indistinct that it was necessary to listen to the heart itself in order to satisfy him that the heart really contracted. The Doctor clearly saw the great interruption to the heart's action, but was unable to say upon what it depended, and ordered some candle to be made of two glasses of sherry, one of brandy, and a pint of good barley water, agreeably flavoured, and of this a small glassful to be given occasionally, and the following medicine—

R Ol. Cajuputi, mʒ.; Mueilag. Acaciæ, ʒj.; Sp. Æther. Sulph. c. ℥xxx; Tr. Capsici, ℥x.; Syrupi Aurant. ʒj.; Mist. Camphoræ, ʒiv.; Aq. puræ, ʒvj. ft. haust. 2da quâque horâ sumendus.

4th, 9 A.M.—About an hour after our visit last night he had a very severe fit, which lasted nearly half an hour, and it was feared it would be his last. He had very little sleep during the night, and had a repetition of the fits. At 9 this morning rose up in bed without assistance, drank off a glass of candle, conversed quite rationally with one of his daughters; immediately after a fit commenced, and in five minutes his existence was terminated.

Sectio cadaveris.—In cutting through the structures forming the scalp there was so much engorgement of the vessels

that a large quantity of blood escaped. On removing the bone, the superficial vessels were filled with blood of a very dark colour; and at the base of the brain the vessels forming the circle of Willis were so well injected, that they could be viewed as readily as if filled with artificial injection. The brain itself, with the exception of congestion, was perfectly healthy; the lateral ventricles contained very little fluid. The plexus choroides was much congested; but this fact was sufficiently apparent, that the congestion of vessels in the interior of the brain bore no proportion to that on the superficies. None of the vessels appeared in any way diseased.

In cutting through the superficial structures upon the chest and abdomen, the same engorgement of vessels appeared as on the head.

The cartilages of the ribs were completely ossified. The pleura on the right side was quite healthy, but on the left side thin firm bands of adhesion, evidently of long standing, held together the pleura pulmonalis and costalis. There was no effusion into either cavity. The lungs were perhaps as perfect a specimen of healthy structure as could possibly be selected, and free of any congestion. On opening the pericardium, the serous membrane lining it, and covering the heart, was quite healthy, and with very slight effusion into its cavity. The dilated state of the aorta could not, however, fail to strike attention; and I then determined to trace the artery throughout its course, suspecting obstruction in the form of ossification or otherwise. The heart itself was rather large, its cavities natural, and all its valves sound, excepting towards the base of one of the mitral valves there was a small spot of ossific matter, which would, however, in no wise interfere with its function. The coronary arteries were traced and laid open throughout their principal branches. Some yellowish white spots were observed between the inner and middle coats; and in the left coronary artery there was a very small spot of ossific matter. In the interior of the aorta there were very many yellowish white spots, in some places forming patches. In one spot, about the size of a sixpenny piece, a softened and ulcerated surface existed; in another spot, about the same size, complete ossification; and as the aorta divides into the two iliaes, perfect

ossification was found, not, however, including the whole circumference of the arteries, but on their inner and posterior part, the outer sides not being ossified, but firmer than natural. The internal coat was destroyed on the surface of this ossification, so that it somewhat projected into the cavity of the artery; this condition presented itself alike in both the iliaes, and extended about an inch along them. The aorta was very little diseased at its upper part, but this increased as the vessel lengthened. The branches of the left internal iliae were completely ossified. The omentum was very largely loaded with fat. The intestines were perfectly healthy, but the terminal branches of the mesenteric arteries were most beautifully seen encircling them. The liver throughout the greater part of its substance, but more especially towards its posterior part, possessed that peculiar appearance termed nutmeg liver; and the openings of the hepatic veins were unusually large. The kidneys contained cysts whose cavities appeared quite distinct, having no communication with each other or the proper cavities of the kidney. Some were completely embedded in the structure of the kidney, while others encroached into the structure of the kidneys on one side, and on the other were covered only by its tunics. They were of different sizes, some containing about a drachm, others half an ounce; but one on the right side contained about four ounces of fluid. The fluid contained in these cysts was of a straw colour. There were about three or four in each kidney. The structure of the kidneys, independent of these cysts, appeared perfectly healthy. The other organs whose characters have not been specified, presented nothing unusual.

[To be continued.]

REPLY TO

DRS. GRAVES' AND STOKES' REMARKS ON DR. HOPE,
IN REFERENCE TO AUSCULTATION.

To the Editor of the Medical Gazette.

SIR,

IN the number of the Dublin Journal of Medical Science for September 1838,

I have just observed the following article, signed with the names of Drs. R. J. Graves and W. Stokes:—

"*Dr. Clutterbuck versus the Stethoscope. Dr. Hope on Auscultation in Valvular Disease.*—In the heading of this notice we have connected the names of the above gentlemen, because, although they are in no way related as authors or colleagues, they have (no doubt unwittingly) joined to injure the cause of auscultation and of science, in their late publications: the one, by attempting to detract from its value; the other, by ascribing to it powers which it does not possess."

"In the next number, Dr. Hope, of whom we wish to speak with the respect which his labours have earned for him, has authorized the publication of a series of diagnoses, made by his pupils after a ten minutes' lecture on the most difficult part of medicine, namely, the valvular diseases of the heart. The pupils were inexperienced, and as far as we can learn, availed themselves solely of physical diagnosis. Their conclusions, in thirteen cases out of fifteen, were 'correct,' although they had, amongst others, to deal with the rare diseases of the pulmonic orifice."

"That the pupils, after having been instructed in Dr. Hope's views of the causes and situations of valvular murmurs, should have come to conclusions such as *he* would have done, is not wonderful; but that these conclusions were correct, we have only Dr. Hope's word for. We shall not examine into the evidence of the conclusions, for we know it to be insufficient; but we object to the whole proceeding, as calculated to revive the often-repeated and refuted objection to the advocates of auscultation, that they neglect the history of the ease and vital phenomena."

"The following considerations we wish to impress on the pupils of the Meath Hospital:—

"First, that the physical signs of valvular disease are not yet established.

"Second, that taken alone, they are in no case sufficient for diagnosis.

"Third, that even in organic diseases the nature and situation of murmurs may vary in the course of a few days.

"Fourth, that all varieties of valvular murmurs may occur without organic disease.

"Fifthly and lastly, that organic disease of the valves may exist to a very

great degree without any murmur whatsoever.

"Of this assertion we shall hereafter bring abundant proofs."

Though I can truly say that I entertain for the two writers of the above remarks no less respect than they obligingly express towards myself—a respect founded on their real professional merits, and not likely to be cancelled by mere differences of opinion between us—yet I doubt whether they are not themselves injuring the cause of auscultation, which they profess to defend, by such publications as the preceding. It might be surmised that they were actuated by a wish rather to depreciate the individual than to uphold the science, when, rejecting evidence, and suppressing his real opinions, to which it will presently appear that they are not, or at least ought not to be, strangers, they attack one who was amongst the very first that introduced auscultation into this country—who, though humbly, has at least zealously fought in its battles ever since, and who has possibly taught it for a much longer period, and to a much greater extent, than has probably been done by the gentlemen in question. Perhaps, too, there is a degree of assumption and arrogance in any two physicians electing themselves *ad cathedram*, and undertaking publicly to pass unqualified judgment on their professional brethren. Perhaps more modesty and courtesy would become high and single-minded votaries of science. Pretermittng these questions of opinion, I confine myself to showing that the gentlemen alluded to, have not, in the present instance, been guided by a sufficiently fine perception of even-handed justice.

They say, "that the pupils, after having been instructed in Dr. Hope's views of the causes and situations of valvular murmurs, should have come to such conclusions as *he* would have done, is not wonderful; but that these conclusions were correct, we have only Dr. Hope's word for. *We shall not examine into the evidence of the conclusions, for we know it to be insufficient.*" Now it is unjust to denounce an individual as in error, on the assumption that he must necessarily be so if he differ from Drs. Graves and Stokes—that he cannot by possibility know more than they, and that therefore examination of evidence is superfluous. More can-

dour and more charity, and more anxiety for the welfare of auscultation, would at least have induced them to wait for the promised evidence. A portion of this I shall now offer. 1. *Presumptive.* When certain rules of diagnosis are found to be so universally applicable as to bring a number of students, without communication, to identical conclusions, even respecting the "rare diseases of the pulmonic orifice," the presumptions are, that they are founded in nature and truth. 2. *Positive.* Three out of nine patients (the total number assembled) have died, and the perfect accuracy of the diagnosis has been verified by dissection, of which I am prepared to give well-attested evidence, with drawings of two, if required. Nor shall I neglect a similar verification in the other cases, if the same calamity should befall the patients; and this will constitute the remainder of the evidence. I can now assure Drs. Graves and Stokes that I am too wary a friend of auscultation to hazard opinions which I am not prepared to substantiate; and though I do reject, and always have rejected, the idea of infallibility as connected with auscultation—there being a small proportion of cases in which, either from the novelty of some of the circumstances or the indistinctness of some of the signs, a degree of obscurity will necessarily exist—yet I can further assure those gentlemen (especially the one who promises the profession a second part of a work on the Chest), that unless they are prepared, like myself, to teach students how to detect, even by physical signs and the pulse alone, the vast majority of diseases of the valves, with their particular localities, and that in the space of a very few minutes—also, how to discriminate inorganic murmurs in almost every instance, and how to account for variations in the *nature and situation* of organic murmurs—they will publish in 1839 as obsolete a work as, in these respects, was published in 1835 by a writer of so much talent as M. Bouillaud—a name which I mention, because they probably lean on his authority in saying that "the physical signs of valvular disease are not yet fully established."

They "object to the whole proceeding, as calculated to revive the often-repeated and refuted objection to the advocates of auscultation, that they neglect the history of the case and vital phenomena." If there be any indivi-

dual to whom this reflection is less applicable than to another, I believe that I have some claims to that distinction. The following is the last, and therefore the most conspicuous, passage in the Introduction to my Treatise on the Diseases of the Heart, published eight years ago—a work with which Dr. Stokes at least was perhaps abundantly familiar, as he is the reputed author of the only unfavourable review of it that ever appeared:—

“With respect to the comparative value of the general and physical signs of disease of the heart, it may be said that Laennec rather undervalued the former and overrated the latter. This was owing principally to the general signs being less perfectly understood, when he studied, than they have subsequently become, in consequence of being investigated with the aid of auscultation. The ardour of his early disciples, who imagined that the physical rendered the general signs superfluous, brought auscultation into some disrepute by the inaccuracy of their diagnosis. But since the stethoscope has taken its proper place as an *auxiliary only*, and the diagnosis has been founded on the two classes of signs conjointly, auscultation has ranked as a discovery which will immortalize its author, and form an epoch in the history of medicine.”

In my lectures I have habitually expressed the same opinions, but in stronger and more explicit terms; and so anxious have I been to do this, that, contrary to my usual habit, I happen to have written out the portion of a lecture which bears on this subject. Though not necessary to my present argument, I subjoin it, in the hope that it may have its uses:—

“There is one point on which I would wish to offer a few preliminary observations. I allude to the estimate which ought to be formed of the utility of auscultation as compared with ordinary symptoms. I am anxious to express distinctly, and once for all, what I feel on this subject.

“After having verified stethoscopic observations by dissection in many hundred instances; been in intimate relations with stethoscopists, good, bad, and indifferent, in this country and abroad during a period of nearly 20 years, I am satisfied that any one who depends on the stethoscope alone, to the

neglect of general symptoms, will commit serious errors in diagnosis. There are certainly many cases in which an application of the stethoscope, *per se*, is conclusive; but there are a far greater number in which it is not. And why? Because its evidence often looks in several directions, and a further clue is necessary to ascertain the *particular* direction in which it bears. The same, exactly, may be said of general symptoms. Now, each of these is the clue to the other, and the concurrent evidence of the two affords information which is perfectly unattainable by either individually—information which renders the diseases of the chest as easy—I am almost tempted to say easier—of diagnosis than any other leading class of obscure affections. It has been urged against auscultation, that, by diverting the attention, it deteriorated the knowledge of general symptoms. The effect is diametrically the opposite; and for an obvious reason—that general symptoms are studied with a new—an extra light. An auscultator, without the use of the stethoscope, ought to be more rapid and accurate in his diagnosis than one a stranger to the science. Finally, a sound knowledge of general symptoms constitutes the shortest avenue to the acquisition of a good practical acquaintance with auscultation. To one so qualified, the superaddition even of a few only of the more prominent and simple physical signs, will give a prodigious advantage.”

Let us next examine for a moment the final “considerations which Drs. Graves and Stokes wish to impress on the pupils of the Meath Hospital.” It may be premised that the good taste of their peroration is doubtful: it reminds us of the advertising sheet—and its self-complacency is not becoming. The Dublin schools are replete with teachers of talent, of industry, and of zeal: their intrinsic merits secure to them their full mead of admiration and respect from all candid minds on this side of the channel; but when the preconizations, direct or implied, of the two gentlemen in question, would import a belief on their part that there is no medical school in the world like that of Dublin, and no school in Dublin like that of the Meath Hospital in particular; and, most particularly of all, that there are no names in the universe like those of Drs. Graves and Stokes; we are re-

miaded of the worthy country squire, who, on coming to London, thought that every body would look at him.

The "considerations," with the exception of the third, are either "not new or (*pace loquar*) not true." All that are not new may be found in my Treatise.

1. *That the physical signs of valvular disease are not yet fully established.* An identical statement appears at p. 336, first edition. But the signs are established to an incomparably greater degree than appears to be known to Drs. Graves and Stokes.

2. *That taken alone, they are in no case sufficient for the diagnosis.* The above quotations from my works will show that there is no novelty in attaching great weight to the co-operation of general signs; but the proposition in italics is novel, and I take leave to affirm, in the most unqualified manner, that it is erroneous. There are some—there are many cases, in which it is possible, in silence, in darkness, without any other aid than the hand and ear, not only to pronounce positively on the existence of valvular disease, but to specify the particular valve affected. I pledge myself to afford any amount of evidence to this fact. I entertain no fear of the assertion being prejudicial to auscultation, and I am heedless of its being considered a boast, since the achievement would be a puny one to the youngest hospital pupil.

3. *That even in organic diseases the NATURE and SITUATIONS of murmurs may vary in the course of a few days.* This applies principally to acute pericarditis, where the organic causes of the murmurs are mutable—a subject in the investigation of which Dr. Stokes has had great merit. Where, however, the organic causes are fixed, the murmurs are only mutable from changes in the concomitant circumstances; and the mutability does not detract from the certainty of the physical diagnosis, but sometimes quite the reverse.

4. *That all varieties of valvular murmurs may occur WITHOUT organic disease.* This subject is considered at page 64 of my Treatise, where I pointed out certain errors of the illustrious Lennec, and explained the real causes of most of the inorganic murmurs. At present I know something more on the same subject. Here again, the sweeping assertion of the writers is fraught with

error. "All varieties," say they! I shall hereafter and elsewhere show that the varieties of inorganic murmurs are very few, and in general easy of detection.

5. *That organic disease of the valves may exist to a very great degree without any murmur whatsoever.* Of this assertion we shall hereafter bring abundant proofs. I was the first, I believe, that ever announced this fact, "A contraction of the mitral or tricuspid valve to the size of only two, three, or four lines in diameter, I have frequently known to occasion little or no murmur." (*Treatise*, p. 57.) Unless, however, our critics are prepared to show that this will not occasion a difficulty of diagnosis in more than about one per cent., they have something more to learn on the subject.

I would now ask Drs. Graves and Stokes whether, if they are really and conscientiously anxious for the progress of science, as a means of benefiting mankind, they do well to assail individuals, who, however humble, are at least zealous, without carefully considering whether their attacks may not, as in the present instance, be gratuitous and precipitate. Surely such favours are showered down in sufficient abundance by the remnant who oppose auscultation*.

I would further ask Dr. Graves and Stokes whether they might not now safely leave auscultation to defend itself. The battle has been fought for twenty years—and won. Unlike homœopathy, unlike mesmerism, unlike every species of quackery, auscultation has withstood the most violent assaults that ever stormed any science, and has emerged strong and refreshed from the struggle. Henceforth, the attacks of its enemies and the indiscretions of its friends are equally impotent. Like waves dashing against a rock, they fall back exhausted in vapoury spray. The public is aware of the issue of the contest; the public has proclaimed its fiat; the public *will* have auscultation; the public *must* be obeyed. Auscultation is dominant in every great school and hospital in London—in every one in the English provinces and Scotland. Auscultators are in the first ranks of profes-

* Of this a ludicrous instance recently occurred to myself, where a totally erroneous report of a diagnosis in a country paper, though spontaneously retracted by the editor in his ensuing number, was copied into others, and circulated amongst non-auscultators, as a subject of triumph and congratulation.

sional success here, and in every great town throughout Britain. The science has spread beyond physicians: it is consistent with my personal knowledge that the most eminent pure surgeons of the metropolis are either competent auscultators, or preparing to become such. It is equally consistent with my personal knowledge, that the great mass of general practitioners are gladly seizing every opportunity of keeping pace with their fellows. As an evidence of their anxiety I may be permitted to state, that, even seven years ago, one hundred, including a few physicians, entered to a course of friendly lectures privately given by myself; and it would not be difficult to assemble an equal or larger number at the present moment, if I had leisure to give private instruction. In the intercourse of private practice they gladly avail themselves of any hints which are courteously and unassumingly offered. It is also consistent with my personal knowledge that many of the senior surgeons in the country are obtaining clever young students from the London hospitals to reside with them, and teach them auscultation.

Under these circumstances, is it dignified, I ask Drs. Graves and Stokes, to assume the offensive? Does it not even imply a doubt of victory? Especially, is it dignified to run a quixotic tilt against an old and respectable physician, to whom medical science is under important obligations, and who might now be safely left to the peaceable enjoyment of his own opinions? Is it worth their while to assail at all the *disjecta membra* of the routed squad? Would they not be better left to the good wishes of Drs. Graves and Stokes, and to the tender mercies of the young hospital students?—for the latter soon learn to look with suspicion on those who would persuade them that they have not the use of their physical senses and common understanding.

Perhaps these gentlemen will say that I have myself assumed the offensive in the proceeding which is visited with their reprobation. I beg to deny this. The diagnosis of valvular diseases with the precision of which I have shewn it to be capable, is a novelty—perhaps peculiar to myself—certainly unknown to the physicians of the Meath Hospital. What is new, if true and useful, ought to be taught; its truth was not credited; it was necessary to

resort to a simple and unequivocal *experimentum crucis*; particular circumstances at St. George's Hospital rendered such an expedient more than usually necessary. Its success was complete, and will be believed, notwithstanding the incredulity of Drs. Graves and Stokes. In all this, I have strictly adhered to my capacity as a hospital physician and teacher. If I have met these gentlemen in public, it is they, not I, who have stepped out of their way; and as I have neither leisure nor inclination for controversy, I should henceforth greatly prefer applauding the well-directed energies of Drs. Graves and Stokes, to entering another protest against a dictatorship from the Meath Hospital.—I am, sir,

Your most obedient servant,

J. HOPE.

13, Lower Seymour Street,
Oct. 15, 1838.

MEDICAL GAZETTE.

Saturday, October 20, 1838.

"L'cet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tueri: potestas modo veniendi in
publicum sit, dicendi periculum non recuso."

CICERO.

ON MEDICAL READING.

It is somewhat singular, that the learned bodies, who have taken upon themselves the care of medical education, and some of whom have stringently ordered the times, and all but the hours, at which lectures are to be delivered, and (they fondly hope) attended, should have left the pupils to occupy the rest of their time according to their own pleasure, without endeavouring to point out any works, by the perusal of which the study of the subjects which they are required to be acquainted with may be assisted. There are some, we know, who will at once exclaim against the idea of recommending the student to read at all, as if it were the greatest of absurdities; but we need only remark, that as all those are persons who have never been in the habit

of reading themselves, they can be no judges of the matter. Some of these worthies speak of reading as if it were synonymous with theory, and the very opposite and contrary to practice, and they talk with contempt of a reading student; they call him *Doctor* if he belong to the surgical class, and sagely laugh and prophesy that he will never learn his profession. They might as well call it disgraceful in a sailor to use a chart for steering along an unknown coast, or laugh at a traveller who consulted a map or road-book.

We cannot condescend to argue with such persons; but there are some, whose judgment on other subjects is both acute and just, who have thrown opprobrium, or at most bestowed but faint praise, on reading, and whose favour we should be glad to conciliate, for this, which we deem to be, when properly directed, one of the most important branches of medical education. We allude, of course, only to the judicious perusal of well-selected books; and holding the opinions which we do, and have so often expressed, on the necessity of a practical study of medicine and surgery, we need scarcely say that we regard the value of books to be, *ceteris paribus*, directly proportionate to the correct practical applications of which their contents admit. In reading such as these, the student, after allowing a fair time for the digestion of his dinner, and the best of his lectures, will employ the rest of each day in the most advantageous manner possible.

There have undoubtedly been many instances in which students, by reading *only*, have failed of learning their profession; but this was their fault, and not the fault of the books they read. There have been as many who have failed of learning their profession by attempting to do it unassisted by books. The error is equal in both extremes; the former are like those who would expect

to become sailors by poring over charts and models of ships at their own firesides; and the latter are like those who would think of finding their way through an intricate country without either map or compass. The right way here as in most other cases, is along the middle; the surest mode of learning medicine is by a judicious and coincident use of personal observation in the wards of an hospital, and of the study of the best authors on each of the several subjects which successively present themselves, as the objects of chief interest.

The case which we at present have in view is that of the vast number of students who are now commencing the winter campaign in our metropolitan hospitals; and more particularly of that portion of them who are anxious to learn enough of their profession to practise safely, successfully, and with an easy conscience; more of it, therefore, than is merely necessary to enable them to squeeze through their examinations. It may be said, perhaps, that the lectures which such a student enters to should be sufficient to supersede the necessity of reading. Perhaps they should; but what is more to the purpose, they do not, and as yet they cannot, effect any thing of the kind. A course of lectures cannot, at the best, be more than a condensed systematic work on the science professed; and even then they are subject to all the errors and faults of such works. There is not, either in the English, or, as far as we know, in any other language, a single systematic work on either medicine or surgery, which can be conscientiously recommended as a constant guide for the pupil in studying the cases in the wards; neither do we yet know any course of lectures which are of themselves perfect for all times and occasions; nor is it probable that such a system, or such a course, will be writ-

ten for many years, perhaps centuries ; for neither medicine nor surgery are as yet nearly enough advanced in accuracy for systems to be formed upon them. The most that either can at present do is to point out the general signs of diagnosis, the general modes of treatment, and the other general characters of the most frequent diseases and injuries ; but for the more detailed descriptions of these, as well as for the histories of all the unusual, or (if we may use the expression) the exceptional forms of disease, the only useful information which the pupil can acquire, is to be found in the monographs with which our medical literature abounds. When it is remembered, too, that these exceptional cases may happen in the practice of any individual to be more numerous than those which are in accordance with the general rule, the necessity of becoming, as far as possible, acquainted with them, will be at once apparent.

But it may be urged, clinical instruction should supply all the wants of the student in cases of this kind. It certainly may do much, but it cannot do all ; it cannot include all the cases in which all the pupils need assistance ; nor are there many teachers who are capable of giving such valuable instruction on every subject as the books specially written upon each can. On the contrary, every one who has attended much to clinical instruction knows how generally the lecturers are in the habit of dealing in a few favourite articles. Besides, clinical lectures, when they are substituted for reading and observation, are open to this great objection, that they may engender and foster idleness in the students, by removing the necessity for the personal study of disease, either by the patient's bed or in the works of authors. So much and so evidently is this the case in France, where the clinical system is adopted in what is called

the greatest perfection, that we have no hesitation in saying that in many, perhaps the majority of instances, it is actually mischievous. Who that has mixed with the Parisian students of the more industrious class, can have failed to observe the avidity with which they note down all the patient's answers to the physicians' or surgeons' questions, then rush to the *Salle de Clinique*, where they write all that their hands can manage of the lecture, and finish all their study of disease by coming over their notes in some reading-room every evening, and cramming up the dogmas of the lecturer without having made a single personal observation ; often without having seen the patient, whose case, in fact, they have only heard. On this system, there is not one student in twenty of those who frequent the Parisian hospitals who gains any practical or personal knowledge of the patients, of whom he sees such crowds.

Now we feel assured, that while clinical lectures should never be neglected, yet by far the best plan for the student to follow is carefully to read the most esteemed monographs on each of the more important subjects that are presented to his notice. After studying and personally examining the cases in the wards, he should refer to his books, and compare the evidence which he has drawn from nature with what is stated in them ; then again, referring to the cases with the additional information he has acquired, and guided to more accurate investigation by the hints he has derived from his reading, he will in a comparatively short period become thoroughly and soundly acquainted with many of the most important points in pathology and therapeutics.

The student, however, should be cautious of allowing himself to be too much occupied with rare cases : his regular mental diet should be composed of those of which in a hospital of average size he

will never fail to find an abundance. In after life he will reap both personal and pecuniary satisfaction in exact proportion to the closeness with which he studies cases of this kind. But in these, as well as in the others we have already alluded to, he will find by far the most satisfactory assistance in the treatises which are specially written on the diseases of individual systems or organs; and (which is of no little importance) he will find the diversity of style in different authors as interesting, as the dull monotony which is sure to reign in the huge system of a single writer is tedious.

We shall take an early opportunity of entering more into detail on the course of reading which we would recommend students of different classes to pursue, and shall point out the particular works best adapted for each. We may take the present occasion just to hint at the contempt of reading and all authority which is too frequently seen in the works of those who, having the absurd ideas we have mentioned during their pupillage, hold them with even greater tenacity, when they themselves become authors. There is much vanity in all this, and more self-delusion; they think themselves fully capable of making discoveries; and, being entirely ignorant of what is already known by others, they live in a constant happy hallucination in meditating on their own originality. We have taken some pains, on two or three occasions lately, to point out the folly of repeating discoveries; and the history of medicine is full of records of time lost in the search after what had been found and laid up in store long before. Much of this contempt of reading has probably arisen from the endeavour to imitate, even to his faults, the great model—John Hunter, forgetting how far his intellect was above the general average. He was, indeed, one

of those few whose minds are of such strength, that they can be at all times trusted without a guide. Yet it may be doubted whether even he would not have done still more, had he been aware of what others had done before him; and had he started from the point at which they left off, instead of undertaking the whole subject *ab ovo*.

The neglect of reading is particularly inexcusable in the present day, when medical literature is so extensive; when the stores of facts are so large, and their value and credibility can be so easily tested. The man who now essays to become a discoverer without reading must be foolish in the extreme, if only for the unnecessary trouble which he gives himself, of going over ground already often traversed, instead of beginning at once where another had left off. But the fact is, the temptation to become, either by fair means or foul, a discoverer, is too great; and too many exclaiming by anticipation, “*perant illi, qui ante nos nostra dixerunt*,” shut their eyes to every thing which would seem to contradict the entire originality of the *discovery* which they have set themselves to make.

How often, too, would a fair consideration of the evidence already accumulated be sufficient to prevent the mistakes which some daily run into! See the history of mesmerism, which in this view at least is most instructive. The evidence collected years ago was sufficient to prove beyond a shade of doubt the fallacy of the system, to all who candidly and impartially weighed it; whilst those who refused to consult it, and trusted to their own imagined powers of observation and reasoning, in a few months built up anew the flimsy fabric, which, as was to be expected, speedily fell, and in doing so covered them with ridicule.

GUY'S PHYSICAL SOCIETY.

THE first meeting of the Physical Society of Guy's Hospital (for the session 1838-9) took place on Saturday, the 6th instant. Dr. Bright in the chair. The minutes of the last meeting having been read and confirmed, an appropriate address was delivered by the chairman, for which we regret that we are unable to make room.

Dr. Guy read a paper

On the Application of the Numerical or Statistical Method to Medicine.

The author adverted to the peculiar difficulties which beset the study and practice of medicine, and proposed to illustrate the nature and source of those difficulties by comparing the means which the medical man employs for the investigation of truth, with those by the aid of which the more exact sciences have been advanced to their present state of perfection. The employment of abstract reasoning was the most simple and certain way of arriving at truth; to this we owed those powerful and perfect instruments of calculation which have been applied with such success to the materials furnished by observation and experiment. To this application we were indebted for the so called mixed mathematical sciences. These sciences differed in their degree of certainty, some of them being scarcely less certain than the result of abstract reasoning itself, and others scarcely more perfect than the least advanced sciences of observation and experiment. Astronomy afforded an example of the highest point of perfection to which science has yet attained; the other exact sciences formed a descending scale of certainty, of which the degrees were marked by the extent to which they admitted of the application of numbers. Dr. Guy then alluded to the science of chemistry, which not many years ago was a mere art, but which the application of a numerical theory—the theory of definite proportions—had raised to the dignity of a science. So great was the certainty which this science had attained, that it was enabled to foretell the changes which would take place between the atoms of matter with the same confidence with which the astronomer predicts the occurrence of an eclipse, or the appearance of a comet. Dr. Guy argued, that if the touch of a numerical theory could thus convert an art into a science—if calculation had conferred such benefits on other branches of human knowledge—the medical man ought to strive to apply the same strict methods to his own conjectural art; and though he admitted the

difficulties which the use of this method would have to encounter, he entertained no doubt of its applicability. Dr. Guy then stated the principles on which he conceived the value of the numerical or statistical method to hinge. They were: 1. That the necessary errors of observation and experiment might be either in excess or in defect, and that the one class of errors would neutralize the other, and leave the actual value of the object or objects observed; and 2. That the same principle would hold good with regard to the things observed, their extreme quantitative values would balance and compensate each other, and leave for a mean result the value of the greater number of the things observed. Having established the general value of the numerical method, and shewn the principles on which it depends, Dr. Guy passed on to the practical application of the method. As a general rule, its application to individual cases was limited and uncertain; but when the mean result of a number of observations was reapplied to as many cases as those from which it had been obtained, or at least to a great number of cases, there was a near approach to certainty. Life-insurances afforded a good example of this application of numbers. Where, again, the extreme numerical values of a number of objects were not very remote from the mean values, the employment of the mean led to useful results. But the extremes also admitted of valuable applications. Dr. Guy instanced the case of poisoning. If a large number of observations had shewn the shortest period within which, or the longest period beyond which, a poison acts, suspicious symptoms arising before the one, or after the other point of time, might be justly ascribed to causes other than the administration of poison. Sometimes, again, it was important to decide between two conditions, each of which occupied one extremity of an increasing numerical scale. Thus, in the case of the static lung test, the smallest weight of lungs which have not breathed, and the greatest weight of those that have respired, having been determined by observation, any number falling short of the one or exceeding the other would give the strongest reason for believing, in the one case, that a child had not breathed, and in the other, that it had. But the practical application of statistical results to individual cases was not their most important use. As instruments of discovery, and foundations for reason and experiment, statistics were invaluable. No reasoning could have any value which was not founded on correct data; numerical data were the most exact, and ought on that account to be employed wherever

they could be obtained. Nor was the science of medicine without abundant materials to which calculation could be applied. Communities as well as individuals, the human body both in health and in disease, the development of the entire frame as well as of its several parts, the functions which it performs, the diseases to which it is liable, the remedies by which disease may be removed and suffering alleviated,—of all these the numerical method was either an accurate measure or an invaluable test. Dr. Guy then shewed that the errors and defects with which this method stands charged, are the errors of observation and experiment, and cannot be considered as an objection to its employment. He illustrated this position by alluding to the error committed with regard to the Government annuities, as well as by a statistical error committed by Bryan Robinson, and shewed that these mistakes were in no degree characteristic of the science of statistics.

In conclusion, Dr. Guy reverted to the question which he had propounded at the beginning of his paper,—What were the causes of the uncertainty of medicine? There was no lack of observations and experiments; there was no want of strong motives to exertion on the part of the members of the profession; there was no want of zeal as to individual cases. Medicine was imperfect because it was too exclusively a practical art. Individual cases created, of necessity, too great an interest in the mind of the observer; for the alternatives of suffering or ease, of life or death, depended on the treatment adopted. This circumstance precluded experiment. If individual cases created a less degree of interest, more pains would be taken to advance medicine considered as a science. It was this practical character of medicine which made the medical man impatient of all those investigations which had no immediate practical bearing. But this practical character of his art created another evil. The ill success often attending the application of general principles to individual cases made the observer despair of the future progress of his science. This despondency was little in accordance with the character of philosophy, which was “to hope all things not impossible, and to believe all things not incredible.” Dr. Guy concluded by stating, that such despondency would not be justified till medicine had attempted to employ the same clearness of definition, the same strict and rigorous methods of investigation, which had raised the more favoured branches of science to such high degrees of perfection. If these methods should be applied without success, it

would be the first time in the history of science that persevering industry, unwearied research, correct and comprehensive reasoning, had been employed in vain.

UNIVERSITY COLLEGE MEDICAL SOCIETY.

THE first meeting of this society for the present session took place on Friday evening: Mr. Taylor, president.

The president delivered the usual introductory address, in which he adverted to the advantages to be derived from a society constituted as this is. The pursuit of medical knowledge, embracing, as it does, so many important branches of science, affords an ample field on which individuals possessed of different mental qualifications can exercise to the greatest advantage those talents with which they may be endowed. It is this fact that renders those opportunities of such importance, in which the peculiar mental powers of each individual can be made available for increasing the knowledge of all, by that interchange of ideas which the public discussion of any question is sure to call forth. The acquirement of the habit of public speaking, by leading us to think for ourselves, and to embody our ideas in words, by which we obtain a clearer notion of them, was also adverted to. The thriving condition of the library and Osteological Museum, which are formed in connexion with the Society, the opportunities the Society afforded for remarks on the clinical practice at the Hospital, and many other points, were most ably considered. When the address was concluded, an announcement of the presents of books which had been made since the last meeting took place. Amongst the donors are the names of Velpeau, Dr. Grant, Professor Graham, Mr. Morton, &c. Votes of thanks were returned to the gentlemen who had thus enriched the library. About forty new members were next proposed. The President then proceeded to award the prize which had been offered to the author of the best essay read before the Society during the last session. The successful candidate was Mr. JAMES BLAKE—this being the second time that this gentleman has had the honour of receiving so flattering a mark of distinction.

At the conclusion of the proceedings it was announced that Mr. Blake would read a paper before the Society at the next meeting.

GLASGOW EYE INFIRMARY.

CLINICAL LECTURES BY DR. MACKENZIE.

October 6, 1833.

Ophthalmia Tarsi.

SINCE 1st August we have admitted on the list thirteen cases of the disease styled *ophthalmia tarsi*—by far the most frequent affection to which the eyelids are liable. Its essential character is inflammation of the glands which surround the roots of the cilia, producing purulent discharge from these glands, ulceration round the bulbs, and destruction of the secreting organ of the cilia. The conjunctiva, the meibomian follicles, and the integuments, are more or less implicated in *ophthalmia tarsi*, and even the cartilage appears ultimately to become thickened.

I must here remark, however, that *ophthalmia tarsi* is a term under which are often confounded two diseases, which in their early stage are sufficiently distinct. The one (*blepharitis glandulosa*) is a catarrhal inflammation of the meibomian follicles and conjunctiva; the other (*blepharitis serofulosa*) is an inflammation of the ciliary glands. These two affections are often conjoined. Indeed, the one leads invariably to the other, so that in chronic cases all the structures which exist at the edge of the eyelids are involved—the ciliary glands and the meibomian follicles, the skin and the conjunctiva, and even the tarsus.

I need not dwell on the symptoms in the advanced stage, as they are familiar to you. The complaint is often obstinate, especially in the chronic and complicated cases; partly, no doubt, from its nature, partly from the bad constitution of the patients, but chiefly from a careless employment of the remedies prescribed. The muriate of mercury collyrium*, and the red precipitate salve†, are the local means I generally order; and if employed with regularity, they are sufficient, in ordinary circumstances, to effect a cure. The lotion is warmed, and used thrice a day. The salve is rubbed into the roots of the eyelashes at bed-time, after a careful removal of the crusts formed by the morbid secretions. These means require to be continued generally for six months, and sometimes for twelve months, in order to prevent relapses, and complete the cure.

Numerous adjuvants have had recourse

to, according to the various phases of the disease, such as cataplasms, nitras argenti, solid or in solution, leeches, counter-irritants, purgatives and tonics. There is a little boy attending, in whom the symptoms were very bad, till he had a pea-issue inserted in his arm, which has been followed by the best effects. To a considerable number of the patients at present attending with *ophthalmia tarsi*, I have prescribed a solution of fifteen grains of murias barytæ in half an ounce of diluted tincture of bark, of which from eight to twenty drops are given thrice a day, in a wine-glass of water. This remedy is much recommended in this disease by Dr. Zimmer, of Prague, and we have certainly witnessed good effects from it.

Syphilitic Ulceration of Eyelids and Inner Canthus.

When you see an adult affected with an inflammation of the edge of one eyelid only, which has continued for some weeks, or it may be months, and has not yielded to local applications, but has rather grown worse, you should suspect syphilis. I have more than once or twice seen syphilitic inflammation of the edge of an eyelid mistaken for simple *ophthalmia tarsi*—a mistake which may be followed by disastrous consequences. A similar caution applies to inflammation and ulceration at the inner canthus; for syphilitic ulceration in this situation is sometimes taken for simple dacryocystitis.

We have two patients at present under treatment, whose cases illustrate these remarks.

CASE I.—Syphilitic Ulcer at Inner Canthus—Penetration of Lacrymal Sac.

A. B. (No. 8404,) an unmarried female, aged 46 years, admitted 10th April, 1838. There is a foul ulcer, with inflamed elevated edges, at right inner canthus. It began three weeks ago, being preceded by a bluish hard swelling, about the size of a split pea. Does not appear to have been troubled with watery eye, or any symptoms of dacryocystitis. General health good. Has had no sore throat or any eruption. Is nursing a healthy infant.

Curetur ulcus unguento simplice. Capiat pilulas Submuriatis Hydrargyri, gr. ij. et Opii gr. ss. duas omni nocte.

14th.—More painful; mouth affected; headache. V.S.; omit. pil.

15th.—Headache relieved. Ulcerated surface presents rather a healthier appearance, but its edges are still raised, hard, and inflamed.

17th.—Ulcer granulating in the middle. Capt. pil. unam o.n.

* R. Muriatis Hydrargyri, gr. i.; Muriatis Ammoniac, gr. vi.; Aqua, oz. vi. M. Solve et cola per chartam.

† R. Hydrargyri Precipitatis Rubri, gr. vi. Tere in mortario in pulverem subtilissimum. Adde Unguenti Simplicis, oz. ss. M. Ft. unguentum.

19th.—Capt. pil. m. et v.

23rd.—Capt. pil. tres indies.

27th.—Capt. pil. unam indies tantum.

7th May.—Ulcer gradually healing.

11th June.—Received a blow this morning on the site of ulcer, which has produced considerable swelling.

Adhibr. hirud. tres.

22nd.—Curetur uleus Unguent. Hydrarg. Præcip. Rubr.

27th.—Ulcer rather increased in size, and more painful.

Rep. pilula m. et v.

17th July.—Omitr. Ung. Hydr. Præcip. Rubr. and utatur unguento citrino diluto.

2nd Oct.—Says that after the blow noticed in a previous report, and the application of three leeches to allay the swelling, the irritation of the leech-bites renewed the ulceration; but that the ulcer again contracted in the months of June and July, from the influence of the pills. The only remains of the old ulcer is a minute orifice opposite inner canthus. It appears to communicate with the lacrymal sac, tears being frequently discharged through it. About a fortnight ago a new ulcer formed on the side of the nose, below the site of the former ulcer. This new ulcer has partially healed, leaving a very irregular cicatrice, without medicine. Right eyelids red and swollen; general health good; sweats profusely in the night; has used no pills for about two months.

Repr. pilula m. et v.

This patient denied having had any primary symptoms. She presented no appearances of having had any sore throat or eruption. The character of the ulcer, and its rapid amelioration under mercury, were the chief grounds for believing it to be venereal.

When she was admitted, had I been asked whether I regarded the ulcer as a primary or a secondary one, I should have said primary; but the supervention of a second ulcer in a new situation must, of course, modify that opinion.

CASE II.—*Syphilitic Ulcer of Upper Eyelid.*

J. S. (No. 8832), aged 20 years, admitted 28th September, 1838. Was born with hypospadias. Has a chancre on the glans, a second on the malformed prepuce, two syphilitic sores on the scrotum, and a suspicious-looking superficial ulcer on right leg. Dates these sores from the month of May. Ten weeks ago a small hard swelling formed on middle of right upper eyelid, which he supposed to be a sty. The

whole of the eyelid is now much inflamed, and rather of a livid colour. It feels hard and tuberculated, and is a good deal swollen. Along its margin, to about two-thirds of its extent, it is in a state of ulceration, and presents a considerable notch just about the middle. Its conjunctival surface is much inflamed, the membrane being thickened, and discharging a considerable quantity of puriform mucus. The ulcer is affected with burning pain, which obliges him to hold a handkerchief to the eyelid to afford relief. Right cornea nebulous, which he attributes partly to ophthalmia in childhood. Pulse 108, small; occasional rigors; complains of weakness; has used no mercury.

Capt. Pilulas Submur. Hydrarg. gr. ii. et Opii gr. ss. duas o.n. et unam o. m.

29th.—Gtt. Sol. Nitr. Argent. gr. iv.

Collyr. Mur. Hydrarg.

30th.—Eye easier.

2nd Oct.—Eyelid less swollen. Mouth begins to be sore.

Cap. Pil. j. tantum indies.

3rd.—Sores on scrotum healing; swelling of eyelid considerably diminished, so that he is now able to uncover the cornea, which is also clearer.

Contr. Pil. j. indies.

4th.—Lid still improves; ulcer on its edge contracting; mouth pretty sore.

6th.—Omitr. pil.

The congenital malformation in this lad consists in a deficiency of the upper part of the prepuce, while the opening of the urethra is not through the glans penis, but close behind it. This variety of hypospadias does not materially interfere with the excretion of the urine, nor even with the fulfilment of the generative function.

The appearances of the eyelid were very characteristic. The general swelling of the whole eyelid, the hard nodulated surface of the swelling, the livid colour, the ulcer spreading along the edge, which at one point it had notched by a complete loss of substance extending even to the cartilage, and the severe pain felt in the part, were all well marked, so that before asking any questions about the patient's previous health, the syphilitic nature of the case was forced upon our consideration. The patient gives a very confused account of the rise and progress of his ailment; but there can be little doubt of the secondary nature of the ulcer of the eyelid.

That the eyelid is a part not unfrequently the seat of syphilitic inflammation, is a conclusion to which I have ar-

rived from witnessing at least ten cases of this sort.

In a case related (Edin. Med. and Surg. Journ. vol. xxxvii.) by Dr. Campbell, of Edinburgh, the upper and lower eyelids of right side were wholly destroyed by syphilitic ulceration. This case was regarded as of very considerable interest at the time of its publication, on account not only of the extent to which the destruction of parts had proceeded, but from the unexpected fact, that the patient experienced neither pain nor uneasiness from the exposed state to which the eyeball was reduced by the loss of its natural covering. A still more remarkable case, however, than Dr. Campbell's, has been published within these few weeks by Dr. Jackson (Lancet, 8th September, 1838), of an old woman living in one of the lanes close by, in whom all the four eyelids have been removed by syphilitic ulceration. Through the kindness of Dr. Jackson I had an opportunity of examining this patient on the 13th ult., and we have here a wax model of her face by Dr. Paterson. I shall embody Dr. Jackson's account of her, with such additional notes as I have taken of her case.

CASE III.—Loss of the four Eyelids from Syphilitic Ulceration.

The patient is a widow of 60 years of age. The entire nose and nasal bones, a considerable portion of the ethmoid bone and of the superior maxillary bones, the inferior turbinated bones, the vomer, and the whole hard and soft palate, have been destroyed by ulceration and exfoliation, so that the nostrils and mouth are converted into one opening, without any sort of division even in front. The opening is bounded above by the ethmoid bone, and below by the tongue; and is capable of admitting the five fingers. The alveolar processes of the upper and lower jaws have been completely removed. Over the centre of the frontal bone there is a large depression, the consequence of repeated exfoliations, and the integuments there are still in a state of ulceration, leaving portions of dead bone exposed. The whole of the upper lip, and the greater part of the lower, have been destroyed by ulceration; but the integuments surrounding the cavern into which the nostrils and mouth are now converted, though puckered and drawn inwards, are perfectly cicatrized. Especially on the left side the finger is easily passed from the situation of the nostril into the antrum Highmorianum.

The eyelids on each side, as well as the eyebrows, have been completely removed by ulceration, and the skin has united to the conjunctiva covering the sclerotica.

The integuments proceed, in fact, from the circumference of the orbits into the conjunctiva bulbi, without forming any fold. The conjunctiva of each cornea is semi-opaque, permitting the dark appearance of the iris to be seen, but not the pupil. The eyeballs present their usual size, form, and consistence, but are almost destitute of motion. When she makes an effort to move the eyes, a slight motion of the skin is observed. Her whole power of vision consists in a perception of light and shadow. She cannot distinguish whether one or two fingers be held before her eyes. The want of eyelids does not cause her much uneasiness when the eyes are shaded, but when she turns her face up to the window, or to a bright light, the eyes are pained. Touching the eyeballs does not seem to excite any pain; they never appear red or inflamed. She does not seem to sleep much, and never soundly. When she goes to sleep, she covers the eyes with a bit of cloth. When she sits up, she keeps her head depressed towards her breast, so as to exclude the light.

On each side there is a small fistulous opening, apparently communicating with the lacrymal gland, from which there is a constant exudation of limpid fluid. When she weeps, which she does frequently, there is a copious flow of tears from these openings down the cheeks, and she says that at the same time she has a kind of burning pain in the eyeballs. The surface of the eyeballs is always dry; never covered with mucosity.

No puncta lacrymalia can be discerned on either side; but below the inner canthus on right side, there are two ulcerated openings which appear to lead into the lacrymal passage. From the feeling of elasticity which pressure in the neighbourhood of the inner canthi, but particularly on right side, yields to the finger, it is probable that the ossa unguis are gone, though in consequence of the firmness of the cicatrice there, and the pain which pressure produces, it is difficult to ascertain this point with any thing like certainty. No other part of the orbit, however, appears to be destroyed.

She seems to enjoy a considerable degree of smell. She, at least, can detect a bad smell, and relishes the odour of snuff.

She speaks with great difficulty, but her daughter understands what she says. It is almost impossible for her to swallow fluids. When she swallows spoon meat she lies on her back, and throwing the morsel down, swallows it with difficulty, and an expression of pain. The tongue, from its constant exposure, is swollen and inflamed. Her hearing is much impaired.

Over the right scapula, there is a large

ulcer, through which several pieces of bone have passed. The whole body is much emaciated. The arms and hands are particularly attenuated, and their joints very flaccid.

The commencement of her complaint she dates fourteen years back. The bones of the head were affected, before any disease appeared in the face. The ulceration, after having destroyed the lower lip, attacked the upper eyelids, then the lower eyelids, whence it spread downwards, and removed the nose and upper lip. The eyelids of both sides were removed before the nose was involved. She blames her husband for improper conduct towards her. She never had any eruption. She had not taken mercury antecedently to the disease commencing in the face. After that, she was salivated by mercury, and took large quantities of sarsaparilla, without checking the progress of the disease. Large portions of bone came away at various intervals.

Dr. Jackson, in his published notice of this case, remarks, that it shows to what a dreadful extent secondary syphilis will proceed, in spite of mercury, sarsaparilla, &c. in a patient in whom the primary symptoms have not been treated with mercury. He thinks the extensive exfoliation of bone could not, in this instance, be attributed to mercury, but to the effects of syphilis.

This case, while it shows the danger of mistaking the nature, or trifling with the treatment of syphilitic ulceration of the eyelids, confirms the observation of Dr. Campbell, that a state of irritation, to the extent which might be anticipated, is by no means the result of the exposed state of the eyes, consequent to the loss of the eyelids. In carcinomatous affections, therefore, requiring the removal of the eyelids, we need not extirpate the eyeball, as has been proposed, in order to save the patient from any severe degree of suffering which has been thought likely to arise from the constant exposure of the eyeball. Were the eyelids removed by an operation, the skin, as in Dr. Campbell's and Dr. Jackson's cases, would unite to the conjunctiva bulbi, and the surface of the eyeball would become dry and insensible.

Mankind have been assured for nearly 300 years, that the venereal disease has been becoming milder and milder, and that they might indulge in the hope of its complete annihilation.

Namque iterum, cum fata dabunt, labentibus annis
Tempus erit, cum nocte atrâ sopita jacebit
Interitu data.

The aspect of this miserable creature, however, whose case I have been narrating to you, would be sufficient to make even a

Fracastorius to shudder. Well might he fear, on looking at her, that the second part of his prediction was about to be fulfilled, and that syphilis had begun to revisit the earth with all the horrors of its first career.

Mox iterum post sæcula longa
Illa eadem exurgit, cæluinque, aurasque reviset,
Atque iterum ventura illam mirabitur ætas.

STATE OF MEDICINE IN GREECE.

THE medical profession is in high esteem among the Greeks. Some few of its members have studied abroad, but these generally settle in the large commercial towns of foreign countries. Formerly they often attained high offices in the state; Capo d'Istria himself had taken the degree of doctor at Pavia.

Some Greek physicians have attended an Italian high school for two years or two and a half, and obtained a diploma *per fas et nefas*; but they are generally established in Turkish towns, where they can hope for better fees than in the exhausted Hellas. They have generally no correct knowledge of surgery or midwifery, and in the practice of physic stick to a few set forms, and enlarge their knowledge by seeing what does harm. The sons and relations of a physician, from their fourteenth to their sixteenth year, visit patients in his company, learn by heart a few Græco-Italian medical maxims, read a modern Greek version of some ancient writer on therapeutics, prepare the medicine at home themselves, and then soon attain the title of proficient, without being able to do any thing more than what with us is comprehended in minor surgery. The greater operations are performed by Rumeliots and Albanians. Midwives and old women who chiefly deal in secret remedies, forms of incantation, and drugs to provoke abortion, and who are sometimes called doctresses, together with Jews from Asiatic Turkey, who sell ethereal oils, &c. against all sorts of ailments, form the keystone of this splendid edifice. The venders of drugs possess about the same quantity of knowledge and conscience, for only Nauplia, Patras, Hydra, and Syros, possess good apothecaries' shops. The prices of medicine are quite enormous, such as one rouble and 90 copecks for two draehms of muriate of ammonia; 65 copecks for a grain of tartar emetic dissolved in six ounces of water; 2 roubles and 40 copecks for a drachm of cherry-laurel water; 2 roubles and 10 copecks for an ounce of oil of almonds; and 5 roubles 70 copecks for eighteen grains of sulphate of quinine. They substitute at pleasure other medi-

cines for those prescribed. Thus, an apothecary sold extract of dulcamara for extract of liquorice*; and occasionally put Extr. Dulcam. ʒiiss. as a *corrigens* into mixtures, without damage, as it was as worthless as the rest of his drugs. The barbers, too, often take upon themselves to prescribe and administer purgatives, and do much mischief, particularly with Le Roi's. The annoyances which well-educated foreign physicians and the few good Greek ones have to endure are very disheartening; superstition and the difference of religion act like powerful drag-chains on the progress of the true art of healing. On visiting his patient, the Greek physician, immediately after feeling his pulse, must know the name and the treatment of the disease; and as Frank travellers all pass for physicians, when hand and tongue are presented to them in the street, they are expected to answer *καλὸ* or *κακὸ*. The patients are so surrounded by their relations, that though they observe no particular delicacy, it is impossible to examine them accurately, especially sick girls. It is unnecessary to mention that when patients are very ill, the clergy are not absent. The physician must give the medicine himself, as nothing would be paid for writing the prescription, if the friends had to fetch the medicine. Long suckling and over feeding children, produce many diseases; so do the frequent greater and lesser fasts, the mean and dirty dwellings heated by chafing-dishes in winter, the bad beds, &c. The sick are almost always ill nursed, and very young children are particularly neglected; if they die before they are seven years old they are not lamented, because they have not yet began to live; while old men, above fifty years of age, have lived long enough. In diseases with delirium, or nervous symptoms, it is impossible to maintain cleanliness, or to do much with remedies, as the patient is deserted on account of the demon supposed to be present, and the friends overwhelm the physician with reproaches, in case of his succumbing in the contest with these spirits. The Greek physicians often make a bargain as to the remuneration they are to receive, and frequently obtain half in advance, not receiving the other half if the patient dies. The poorer class sometimes show their gratitude by sending fruit, eggs, &c., while the more opulent are very unthankful. Physicians who

wish to cut a figure are obliged to demand high fees, and by all means appear in public with a number of attendants. The physician may adopt any system and any method of treatment, as he is not subject to any responsibility. Medicines here produce their effect more quickly and strikingly, and wounds heal more easily.

One of the commonest remedies, and first employed in almost every ailment, is bleeding; it is for the most part only from four to six ounces, as even the healthiest persons, from early childhood, are generally bled four times a year. So small a quantity is, of course, insufficient in really inflammatory diseases, and then the patients are exhausted by a repetition of these small bleedings. The *primæ viæ* are then cleaned out with purgatives; castor oil, Epsom salts, senna, manna, cream of tartar, rhubarb, jalap, and a plant of no great power, called *ξηρόχορτον*, being indiscriminately employed. Leeches, which are scarce and dear, are not unfrequently put on, to the number of one or two, but without any particular intention of local bleeding. After the purging, which is often reinforced by a clyster of sea-water or common salt, the patient generally takes kermes mineral, in the dose of from gr. ss. to gr. j. a day, with nitre and sugar, or in a mixture with Hoffman's Liq. Anod. The treatment is concluded with a mixture of bitters and aromatics, such as commonly grow in the country—balm, mint, dandelion, orange leaves, marjoram, thyme, chamomile, &c.

In inflammations and continued pyrexia they allow venesection until the eighth day, but not beyond that period, even in the most pressing cases. Resolvents and diaphoretics are almost unknown, nor do they pay much attention to crises or critical evacuations.

In nervous fevers they employ, without selection, either Infus. Aromat. with angelica and Hoffman's anodyne solution, or kermes mineral with blisters and sinapism; but these medicines seldom produce a favourable termination, because the patients have become incapable of a struggle through the preliminary bleeding, which is employed in these cases also. In intermittent fevers, besides bleeding and purgatives, they employ quinine to the extent of fifteen or twenty grains during the apyrexia; but in bad cases, such as occurred, for example, frequently in 1829, their small bleedings are insufficient; and they do not trouble themselves about the sequelæ, taking no note of swellings of the spleen. It is thought that cold fevers were not so common during the Turkish sway, because care was then

* It would appear from a hint in the German original, that this substitution was not wilful, but arose from his confounding the first parts of the words *dulcamara* and *glycyrrhiza*, both signifying *sweet*—an explanation which may also apply to his using *dulcamara* as a *corrigens*.—*Translator's Note.*

taken to root up the Euphorbiæ. Gastric and rheumatic ailments are destroyed with the same sword, namely, bleeding and purgatives; and rhubarb often constitutes the whole treasury of a Greek physician. In violent rheumatic and arthritic maladies, in diseases of the skin, and in erysipelas, oils and balsam are employed externally, and, in case of need, Turkish baths; but most of these were destroyed in the war of liberation. The natural healing springs at Thermopylæ, Cimolos, Melos, and Cythnos, are frequently used. Capo d'Istria caused those of Cythnos, which are much frequented, to be examined by Kyber, Cabisol, Zuccarini, and Mahu; and Dr. Thraemer gives the principal results of their investigations from the *Courrier de la Grèce*, of July, 1830; he does not seem, however, to be acquainted with Landerer's fresh researches. Establishments like those of regular watering-places have not yet been thought of, but at Ricord's request the Emperor of Russia caused a considerable quantity of medicine to be delivered for the use of the visitors of the springs in 1833.

The primary appearances of syphilis are treated with calomel, corrosive sublimate, and mercurial inunction, until dangerous salivation, mercurial disorders, and secondary diseases, are frequently produced, which, however, thanks to the fine climate, do not always cause the frightful destruction that might have been expected. Of fifty-seven girls of the town, the Russian physicians found that fifty-one were infected; and of these many were labouring under condylomata, and ulcers about the anus, which is also frequently the case with married women (*e concubitu detestabili*). In gonorrhœa, the Greek practitioners do not trouble themselves about the proper treatment of the inflammatory condition; they give diuretics (cantharides being in particular misused this way), and the Decocti Graminis, (Decoct. of Triticum repens, or couch grass), nitre, and cubebs.

Phthisis, which is here of rarer occurrence than with us, is not retarded in its last and rapid stage by the quinine and opium given with the hope of strengthening and soothing. An electuary made of aromatic herbs, with quinine, opium, and honey, is called *Mantschuri*.

Scurvy is often produced by the use of mercury, and is merely palliated by the external use of sulphuric acid. Cases of worms are treated indiscriminately by scammony from Lesbos, or colocynth from Cyprus. There is a secret remedy called λεβδιχόνδος, which is perhaps the same thing as Helminthocorton, or Mousse de Corse.

In ascites and hydrocele, puncture with a scalpel is often used; otherwise the only remedies are the expressed juice of the squill and onion. The Scilla maritima, which is there a common plant, is called κουρβόρα σκίλλα; but ὄρχιδα σκίλλα is the Satyrium orbitidis of Linnæus.

In colic, with or without diarrhœa, dry cupping is applied, which is often preceded by turning about the navel (*γυρίζειν τὸν ὀμφαλόν*); that is to say, an old woman places her fore finger on the navel, and then turns herself round the patient thrice, at the same time staring him in the face. Hæmorrhage from the uterus is treated with cinnamon; alum being said to produce barrenness.

Savine and cantharides are much misused in amenorrhœa; if the catamenia are too frequent, toasted spiders are given in powder, or, in spring, the cast sloughs of snakes, or else fresh walnuts.

In cramps, opium is administered, unless the aid of the clergy is sought; but the preventive is to wear stones taken from the head of the wild ass; and before an expected attack, the patient holds an ass's tail in his left hand. Lunatics are sent to the convents.

Erysipelas is not treated with internal remedies, but, by means of poultices, is forced into the suppuration, which is often frightfully destructive.

In jaundice, after bleeding, the yolks of eggs are taken, boiled with almond or nut-oil, and saffron; or saffron in an emulsion of melon seeds or linseed. The almond of an ox tongue, toasted and powdered, is said to have been of advantage occasionally.

Acute diseases of the skin are rare among children, not excepting small pox; and the Russian navy physicians exerted themselves in diffusing vaccination.

Spring courses of physic are frequent; consisting of bleeding, purgatives, the application of two leeches to the anus, low diet for two or three weeks, and several doses of Lemnian earth taken daily for the same period. Patients are allowed for drink decoctions of barley, bread, rice, lemon-water [distilled lemon-peel water?] and syrup of maidenhair; macaroni and rice are given as food, and the patients are often injured by being allowed to eat fruit even when unripe. They also have fish, shell-fish, and mutton; fowls and lamb are considered as delicacies fit for the conclusion of the course. The Greek physicians, not excepting the better educated ones, leave surgery, even in its higher branches, to the inhabitants of the Rumeliot villages of Charmora and Argyrocastron; who, without anatomical knowledge, have a certain dexterity trans-

mitted from father to son, and from their very want of theoretical knowledge, fear no danger. These men are not deficient in the art of pulling the long bow; one of them, for example, would have it that he has drawn out a comminuted os femoris, and substituted in its stead the thigh-bone of a dog.

Swellings are treated either with emollient poultices or with stimulating ones, made of roasted onions, sugar, and mustard; swellings of the testis are not excepted from this method, as they always attempt to promote their spontaneous opening. Irritating ointments are applied to ulcers, and cupping-glasses or a leech to the adjacent parts.

Operations for hernia are performed without the least attention to the indications. Nor is the surgery of the eye better understood, for of four hundred children in the orphan-house at Ægina, nearly one-half had lost one or both eyes by staphyloma, inflammation of the cornea, &c. after Egyptian ophthalmia. The practice of midwifery is not to be thought of by physicians, particularly by foreign ones. In difficult labours, the midwives are said to place the woman by turns upon her head and her feet, and to press and bind the body in different directions: if this is of no avail, the husband is called in, who strikes her thrice with his slipper on the back, and cries out, "I have burdened you, I will unburden you!" and if nature proves insufficient, both mother and child die. The navel-string is torn off, or rather rubbed off with the nails, and the blood carefully stroked out of the part remaining on the child. After this, attempts are immediately made to bring away the placenta, while the woman is made to blow continually into an empty bottle; and if the after-birth is not easily expelled, some one catches hold of the woman's abdomen and presses it stoutly. The new-born child is besprinkled with ashes or salt, and is not cleaned for days or weeks; nay, one may see children a year old who have never been washed or bathed. The juices of plants, commonly given in Germany, are seldom employed in Greece; but opiates are used, or abused, for every uneasiness. Women in childbed have generally no medicine except anise tea, or a decoction of maidenhair; but venesection is sometimes employed if the lochia are scanty. The pudenda are covered with a poultice of rose-leaves, honey, and wine, or brandy, or sometimes alternately strewed with aromatic herbs dried and powdered, until the ninth day. No one goes out before the fortieth day. Spices, such as cloves, cinnamon, &c., inserted, together with cotton or wadding, are used against pro-

lapsus and obliquity of the uterus. Dr. Thraemer gives an account of the first labour of a woman aged 16, where he was the accoucheur, and where he was deserted by two Greek midwives, whose silly doings he would not give way to.

In 1829, the first real quarantine establishment was set on foot at Ægina, which was followed by others at Lyros, Hydra, and Tipareus; but the irregularities in them are said to have been frequent.

In 1828, hospitals were established for the regular troops, for 125—150 men at Nauplia, and for 60—75 at Patras. The civil hospital at Nauplia, founded in 1827, and restored in 1829, was given up to the French troops in 1832. The town hospital at Syra is poor in money, and not well off in other respects. The infantry should have six physicians, and the two squadrons of cavalry one; but these numbers have never been kept up. The medical officers, too, neglected their duty, and were not well overlooked. A physician whom they had in the ship Hellas, and another in a frigate, soon resigned.

In 1829, Mahu established a central apothecary's shop, and at a later period prepared artificial mineral waters. For forensic medicine nothing has been done.

[From a review of Dr. Thraemer's inaugural essay, "De artis medicæ in Græciâ statu hodierno," in the *Zeitschrift für die gesammte Medicin*, for January 1838. Dr. Thraemer was first physician in the Russian fleet, and visited Greece from 1828 to 1833. His treatise was published in 1836, and the reviewer observes, that since the author left Greece, several skilful German physicians, such as Dr. Wibmer, have been appointed to situations in the University of Athens, as well as the court apothecary, Landerer, &c.—TRANSLATOR.]

CLINICAL CLERKSHIPS.

To the Editor of the Medical Gazette.

SIR,

SOME months back* I endeavoured, through the medium of your valuable journal, to direct the attention of hospital physicians and surgeons to the better management of clinical clerkships. Whether those observations have ever met the eyes of that class of our profession for whom they were intended; or whether, if they have, they may be the means of successfully directing their attention to this subject, I cannot

* MEDICAL GAZETTE for April last.

say; but I do at least hope that the admission of my letter into your journal evinces a tacit approval, on your part, of its contents; and if such be the case, it may not, I think, have been written in vain.

Some persons may think the subject of clinical clerkships one of little importance. Do such persons know what is the clinical clerk's office? It is diligently to investigate the history and symptoms of disease at the bed side of the patient, and then and there to put them beyond the uncertainty of memory, by committing them, together with an account of the treatment and its effects, to paper.

As regards the clinical clerk himself, this is perhaps the most important period in the study of his profession, and the labour that it will cost him to get at the history of each case, accurately to describe and systematically to arrange the symptoms, will be amply repaid to him in his future career. "Professional tact" may be acquired by habit and by practice, but that thorough knowledge of disease under all its bearings, which alone can direct the physician to the proper use of remedies, can only be acquired by him who has constantly and laboriously surmounted these difficulties. To such a one, when called to the patient's bed-side all is clear and distinct, whilst the mere man "of tact" aims at random, and not only runs the risk of not hitting his mark, but of inflicting injury when he should have bestowed relief.

Such, then, are the advantages of the clinical clerkships in the education of the gentlemen holding these offices. What will be the influence of a well-kept register of cases upon the other students of an hospital? Some, perhaps, will say, to make them idle, by encouraging them to trust to others for investigating disease instead of to themselves. It might as well be asserted that a well-written history is a bad thing, because it discourages people from themselves searching for and compiling its materials. The industrious medical student who is obliged to move through the usual curriculum of education in the limited time allowed for that purpose, finds in a large hospital much to be done, and much to distract and divide his attention.—"Ὁ βίος βραχύς, ἡ δὲ τέχνη μακρὴ, ὁ δὲ καιρὸς ὀζύς." When he has accidentally or necessarily omitted for a period to watch over a case, or when his attention has first been drawn to it at an advanced period of its progress, I need not say how inestimably useful to him will a good account of the case prove.

I may here likewise add, that not a few

of those cases which are most instructive are so acute in their progress, and so severe in their symptoms, as to preclude the possibility (at least in point of humanity to the sufferer), of each student fully investigating the case for himself. He gets a glance at the patient when the medical officer makes his visit, and for the rest he has nothing to depend upon but the accuracy of the clinical clerk's report.

But perhaps the most serious light in which to view this subject is, the vast importance of the due administration of the clinical clerk's office to medical men and science generally, and through them to the public at large.

The medical science, as regards diagnosis, rests on the accumulation of evidence; and so, indeed, does the therapeutical part of our art; for nearly all remedies are experimental; by which I mean to imply that there is seldom such a natural relation between any remedial agent and a disease that we can *à priori* say that such a remedy will certainly cure such a disease. Our treatment in similar cases is directed by past experience—in dissimilar, by analogies. Now, had the vast number of facts which are daily, hourly, nay, momentarily transpiring at our large hospitals, been carefully, diligently, and impartially collected, what an immensity of knowledge would they have contained. Before such a mass of knowledge how quickly would many of the charlatans of the present age, with their misnamed sciences, have disappeared. Upon how much surer footing would many points of diagnosis have stood if established by the concurrent testimony of all, instead of by that of a few individuals most (but it is to be feared not all) actuated by an honest professional zeal. As I have before stated, it is experience alone that can prove the efficacy of any remedy; surely, then, it is a matter of no small importance to the profession at large, and to the public generally, that that experience should be obtained in the shortest possible time, and from the greatest possible variety of sources. Then, as to changes of structure found after death, the relations they bear to the symptoms during life, and the part they may have acted in the destruction of life, it is in hospitals chiefly that we must look for information upon this subject, and to well-qualified, industrious, and zealous clinical clerks, for so compiling that information as to render it available to the present and future ages.

I remain, sir,

Your obedient servant,

PHILOMATHES.

London, 3d October, 1838.

HYSTEROTOMY.

DR. GIBSON, Professor of Surgery in the University of Pennsylvania, has been successful a second time with this operation upon the same woman. It was performed on Sunday, November 5, ten hours after labour had commenced. The child's head presented at the inferior strait, and the membranes were ruptured. Some difficulties were experienced in extracting the fœtus, owing to the sudden and violent contractions of the uterus; this was, however, successfully accomplished by Dr. C. D. Meigs. We saw the patient a few days after the operation, through the politeness of Dr. George Fox, under whose care she was, and to whose judicious management of the after-treatment much of the ultimate success may be attributed. She was doing very well, and the wound healing rapidly. She told us she had suffered much less than when delivered *per vias naturales*. It is now eight weeks since its performance, and the woman has perfectly recovered, without a single bad symptom. The infant is in excellent condition.

This is an additional proof of the propriety of prompt action, when this operation is once determined upon. For a very interesting account of this woman's first labour, when cephalotomy was performed, see North Am. Med. and Surg. Journal, No. xxiv. Oct. 1831, communicated by Dr. Fox.—*Philadelphia Medical Examiner*.

RESECTION OF THE HEAD OF THE HUMERUS.

At a recent sitting of the Academy of Medicine, M. Bandens presented a preparation of the heads of humeri, which he had removed in consequence of gun-shot wounds received in Algiers. Three of these cases were completely successful, and the movements of the arms were in part preserved; two had seemed going on in every respect well, when they were carried off by cholera; and the sixth died of hæmorrhage.—*Archives Générales de Médecine*, May 1838.

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO HAVE RECEIVED CERTIFICATES.

Thursday, October 4.

William James Cowper, Guernsey.—George Jackson Longbottom, Liverpool.—Richard Brown, Wigan, Lancashire.—William Joseph Davies, Abercarn, Monmouthshire.—Thomas Henry Sharples.—John Waterloo Todd, Woburn.—Charles Bull, Brides, Suffolk.—John Snow, York.—Charles Edward Blair, Colchester.—George Robert Wyatt, Oxford.

Thursday, October 11.

Edward Harman Maul, Southampton.—Wm. James Bodger, Brentwood, Essex.—Ansell Ball, Horncastle.—Robert Harrison Bowness, Pooton-le-Fylde.—Richard Turnock, Leek, Staffordshire.—David Lloyd.—Thomas Sanderson, Bala, North Wales.—George Newnham Woolley.—Clement Mears Harris, Dursley.—Frederick Gaskell, Chelsea.—Richard Alford, Taunton.—Frederick Marston, Hull.—Thomas Millthorpe, Arkendale.—Robert Blakiston Embleton, Sunderland.—James George Da Cruz Denham, Calcutta.

LECTURES ON SURGERY,

DELIVERED AT ST. THOMAS'S
HOSPITAL,

BY THE LATE MR. CLINE;

With Notes.

[THESE lectures were written by Dr. Wilkinson when attending Mr. Cline's lectures, in the years 1787-88-89.

Extract of a letter from Dr. Wilkinson, dated Feb. 6, 1838:—"They (these lectures) are the results of six courses of lectures I attended at St. Thomas's, in 1787, 1788, and 1789; and I am in hopes I did not omit any interesting part of Mr. Cline's valuable observations. The one I had the pleasure of giving you is the repeatedly corrected copy."]

LECTURE V.

On the Nature and Treatment of Hernia.

Hernia is a tumor formed by some part of the contents of the abdomen so protruding as to be seen and felt externally. Sometimes it is formed by one viscus, or part of one only, or by more than one: an enlarged spleen comes under the definition. We have not only herniæ of the abdomen, but of the brain. We shall at present confine ourselves to the consideration of the former of these.

Several circumstances concur to the formation of herniæ. From the very strong efforts which the very powerful muscles of the abdomen are constantly making, they produce considerable pressure on that cavity, which frequently occasions certain parts of the peritoneum to give way; some being more liable to do so than others, as where considerable vessels are passing out. Herniæ, therefore,

more frequently happen where vessels are passing from the cavity of the abdomen, than at other places; also that part of the peritoneum attached to the iliacus internus muscle, just above Poupart's ligament, is found adhering more loosely than in other places, and, of course, if considerable pressure is made on this part, the viscera are liable to protrude. Herniæ, from their different situations, are distinguished by the names of *inguinal*, *scrotal*, and *bubonocoele*; which last, when so far enlarged as to be in the scrotum, is called *scrotal*, which is the same as the *inguinal*, only protruded further. If the tumor is at the upper part of the thigh, immediately at the bend between it and the abdomen, then it is called *crural*, or *femoral*. The peritoneum having protruded immediately under Poupart's ligament, might be considered as *inguinal*, but is not called so. A tumor very frequently forms at the navel, where the peritoneum has not such perfect support as at other parts: it is then called *umbilical hernia*, or *exomphalos*. It has happened in perineo*, from a protrusion of peritoneum at the superior part of the foramen ovale, called *hernia foraminis ovalis*. There is also another described, found only to exist in the female, a tumor formed in perineo, between the vagina and rectum. Besides these, we have sometimes protrusions between the several muscles of the abdomen, as in the linea alba and semilunaris: when between any of these parts about the abdomen, it is called *ventral*. Almost all the viscera have been occasionally found to form these protrusions; to this there are some few exceptions, of which the duodenum is one, being so firmly bound down at the poste-

* The thyroideal, or hernia of the foramen ovale, can scarcely be considered as perineal; besides which, such a description would be apt to confound it with the true perineal hernia, where the parts protrude in man between the bladder and rectum.—C.

rior part of the abdomen, and so firmly confined to the cellular substance; nor have the kidneys* or pancreas at any time been found in hernia, both being confined posteriorly. All the other viscera have been found to make a part of them, as the stomach, liver, and spleen, which have been so far displaced as to form these tumors. The large intestines are very much confined, but they are every now and then found to form hernia.

Hernia are also frequently named from the contents; as when formed by intestine, *enterocele*; if by omentum, *epiplocele*; and when by both, *entero-epiplocele*. Also the urinary bladder has been known to form one of those tumors—then called *hernia cystica*. This can only happen in the inguinal and crural hernia: it could not be further displaced.

The contents of a hernia may be frequently determined by a careful examination. In an *enterocele*, the tumor is always regularly rounded: on pressure, there is a great deal of elasticity, from the quantity of air it contains; and the roundness of form, and elasticity when pressed, is uniform. When *epiplocele*, it is rather of an oblong form and irregular feel; if you grasp it in your hand, you feel an irregular substance underneath, readily moveable in the hernial sac. When of the compound species, you have the regular round form of the *enterocele* and elastic feel; and on grasping the tumor, you feel the irregular substance within, which is not distinguishable if there is intestine alone. The *hernia cystica* is distinguished by the tumor diminishing every time the urine is voided: if it has not entirely subsided after the patient has discharged his urine, by pressing it will disappear, the remainder of the urine being passed into the part of the bladder situated in the pelvis. In the *hernial sac* there is a good deal of variation, which we should have an accurate knowledge of, otherwise embarrassing circumstances would arise in operations for this complaint. A hernial sac is nothing more than a protrusion of part of the peritoneum, forming a projection through some aperture: and the structure of this must correspond with that of the peritoneum. The portion of peritoneum thus protruding soon forms adhesions to the surrounding parts, though when first it passes out of the abdomen it will be unconnected with the parts

where it is situated, but it soon acquires union, in a greater or less degree, to them, sometimes so inconsiderable as to admit of the sac being moved upwards and downwards; at other times it is hardly moveable at all. The aperture through which it passes is commonly smaller than the size of the parts situated beyond, which therefore has the name of orifice or mouth of the hernial sac: you have a dilated bag with a narrow neck. It is the same in an umbilical hernia; that part where it passes through the aperture of the navel is smaller than that beyond. We also find these orifices become very much thickened, much firmer in substance than the other parts of the sac. This increase of thickness arises from the pressure that the peritoneum receives at that part.

The hernial sac varies in form also, being generally oblong, but sometimes round, as in ventral hernia. We sometimes find that a hernial sac is not only contracted immediately at the orifice, but has also contractions situated in other parts—sometimes two or more are to be found. These are circumstances necessary to be attended to, for in performing this operation we every now and then meet with such contractions, by which the stricture is sometimes formed; hence, though the ring be dilated, it is insufficient for the return of the contents: these contractions must likewise be dilated. These contractions are difficult to account for: that at the neck is very easily explained; the others, I believe, are formed from the hernial sac being from time to time elongated. You may have two or three or more contractions from fresh protrusions taking place from time to time; or they may be formed from patients wearing trusses, and irregular pressure being produced at different parts; however, in whatever way it may happen, it is necessary we should be acquainted with their situation, for sometimes the intestine passes down through several of those. In the operation you find the intestine may be incarcerated by these different contracted parts, so that it may be necessary to dilate them; and they are not unfrequently out of sight, so that you cannot get a view of them from an external incision, and can only ascertain their existence by passing in your finger. Besides these contractions thus occasionally formed, another circumstance every now and then happens—viz., *membranous bands* pass from one side of the sac to the other, forming transverse partitions; thus, a large hernial sac having been some time partly inflamed round these membranes, a portion of intestine may be so far entangled, that, without our being apprized of the cause, it would be difficult to extricate

* Dr. Menro says his father saw a boy, six months old, in whom both kidneys passed through large apertures in the muscles of the loins, and were covered by common integuments only, and the apertures were so large, that the kidneys could be easily reduced, but were with difficulty retained within the abdomen. (Vide Lawrence on Hernia.)—C.

it. There is an instance related in the *Memoirs of the Royal Academy at Paris*, where such a band was situated just at the orifice of the abdomen, where, after the intestine was supposed to be returned, the symptoms of obstruction of the bowels came on, and the patient died. It was found that the folds of the intestine were entangled in the band, so as to keep up the symptoms of strangulation. We ought, therefore, to see that the orifice is perfectly free after the operation, and that no part of the intestine is embraced or entangled there.

Herniæ are much more frequent in men than in women, which may arise from men being accustomed to much greater exertions: the pressure these give rise to on the contents of the abdomen subjects them more frequently to this complaint. Another cause is the large size of the abdominal ring. But in women, the space situated under Poupart's ligament is larger than in men, which causes them to be more subject to crural herniæ. Women are apt to conceal herniæ, from motives of delicacy; hence we may seldom see them than in men. The formation of herniæ is most commonly very gradual: the tumor comes on almost imperceptibly, is very small at first, and the protrusion is very gradually increased, till at last it becomes of such size that the patient discovers it. Mostly while it is forming the patient is subject to cholicky sensations, from obstructions to the passage of the contents of the intestines, and which he remembers to have had before the tumor appeared. On a sudden the patient feels something give way, and, on examination, immediately discovers a tumor: this happens sometimes from a violent fit of coughing, sometimes from a blow being received. Laceration has been produced in some part. The abdominal ring may be torn from severe blows; and from the efforts of the abdominal muscles afterwards, a protrusion has followed. Herniæ vary in their size, being frequently so small as hardly to be distinguished, and at other times they are very extensive; when very large in size, it is generally from their having existed a great length of time without the patient wearing a truss, and thus the greatest part of the abdominal viscera may come to be contained within the sac. I have seen a scrotal hernia extending to the knees, so large as to contain half the viscera: this man was only capable of wearing a petticoat. This arose entirely from neglect. In hernia of such considerable size, the aperture is very large; so that, having reduced the viscera, you may thrust your whole hand into the cavity of the abdomen.

Herniæ may be considered in three diffe-

rent states—as *reducible*, *irreducible*, and *strangulated* or *incarcerated*. By the first we mean where the contents of the hernia may be returned; by the irreducible, when, from every effort we make, by varying the position of the patient, we find it impossible to return them: in the strangulated state, the parts are not only irreducible, but in a state of inflammation, the contents of the hernia being inflamed.

The reducible state is very various: it may be so easy, that varying the position of the patient may affect it. In other instances, though not so easy, it may be returned by pressure in a horizontal position; while it sometimes requires considerable efforts, long continued, and in a favourable position.

The irreducible state of hernia may arise from two causes—an alteration in the figure of the parts after they have descended, or adhesions taking place between them and the hernial sac. The irreducible state of hernia, on account of the altered figure of parts, mostly arises in the omentum; thus the patient shall have an epiplocele, and the omentum is suffered to remain in the sac, without his attempting to return it: as the abdomen of the patient is increasing in fatness, so is the omentum; that situated in the bottom of the sac will become more bulky than that within the narrow orifice; therefore the enlargement of the omentum will be similar to the growth of a vegetable in a bottle with a narrow neck. It also happens more frequently from some accidental inflammation, arising and producing adhesions between the sides of the omentum and hernial sac. If it produce adhesions between the two, it must ever remain so, it being impossible to return it.

The strangulated state is when the contents of the sac become inflamed, and consequently increased in size, which occasions the difficulty, or frequently the impossibility, of returning them into the abdomen; or, in a large protrusion, there may be more situated in the sac than will allow of the intestines performing their functions: the faeces accumulate, produce obstruction which occasions inflammation, and when once begun, it goes on increasing. This strangulated state of hernia is at once known from the symptoms which immediately arise. As soon as the functions of the intestines are impeded, it is followed by cholicky sensations, occasional sickness at the stomach, soon followed by vomiting. The tumor becomes very tense, and exceedingly painful to the touch. These symptoms are soon increased: the patient becomes exceedingly restless; has a hot dry skin, with a quick strong pulse; the nausea and vomiting are

more frequent; tenseness of the tumor still further increased, and the pain gradually getting more and more severe. These symptoms progress for a time, and the inflammation is extended into the cavity of the abdomen, in consequence of which it becomes tender, as well as the tumor; general tension takes place; the pulse becomes still quicker than before, the patient extremely restless, the stomach throwing up every thing as soon as received; during which time there is a constipation of the intestines, for the peristaltic motion becomes entirely inverted, till at last the patient vomits up bilious matter, the contents of the small intestines; the tumor is made larger by serum being thrown out from the inflamed vessels into the sac, which assists in distending it. Intestine or omentum being in this state, cannot continue long so without mortification ensuing, unless the pressure is taken off, by being returned into the abdomen, or the operation speedily performed. Hiccup often precedes, and indicates that mortification will soon take place. It is not a symptom of the actual presence of gangrene, as some authors say. The intestine being in the same state as if there was a ligature round it, stopping all circulation, gangrene takes place, which is known from the pulse changing from a quick and full to a slow soft one; also some irregularities and intermissions are every now and then felt—perhaps once in twenty or thirty strokes. To one who has not seen a number of these cases, the pulse would seem very natural, but it is the pulse of debility arising from gangrene of the intestines. At the time the pulse sinks the pain is less than before, the patient becomes quite easy, and the part which was before tender is now quite dead; he finds a great relief of all his symptoms, the tumor is soft, and not at all painful. I have known men of considerable experience deceived by these symptoms. Whenever there have been symptoms of violent inflammation, we ought to attend with the greatest care to every circumstance relating to the patient, that we may not be led into error, attending particularly to the state of the abdomen; if all the other symptoms appear favourable, and on examining the abdomen you find it tense, and some degree of pain on pressure, you may suppose the patient in the utmost hazard. This I have seen so often, that I am always apprehensive of mortification when the patient expresses great ease; it may also be discovered by feeling the pulse for a length of time: if there is an intermission in thirty or forty strokes, it is a sinking pulse, the consequence of mortification,

rather than a pulse of health. There is also a glassy appearance in the eye. Though you may succeed in returning the hernia, if the patient's abdomen does not become soft, and continue so afterwards, danger is to be apprehended.

The causes of hernia are various. There are some fanciful ones related by authors. Some think it may be produced by particular diet, as eating too much oily food, which contributes to relax the parts so much that they readily protrude; hence some have observed that monks are more subject to hernia from this cause; but I rather think it is from their sedentary lives, which produces relaxation. Therefore we find that patients in a convalescent state are very apt to have hernia formed at that time; also inhabitants of hot climates are more subject to hernia: in either case, if a great degree of relaxation exists in the habit, whether from illness, state of constitution, climate, or the age of the patient, they are more subject to the complaint. Herniæ are therefore more common in infants than at other periods. While the parts are in this relaxed state, any considerable efforts are liable to produce hernia. Herniæ are also sometimes formed suddenly, from a violent blow being received, and lacerating a part, so that a natural aperture becomes increased in size—as the abdominal ring.

In the inguinal hernia the protrusion of the peritoneum takes place at the abdominal ring, and the course in which it passes is exactly that of the spermatic cord. The hernial sac in a serotal hernia takes the same course, passing on the fore part of the vessels, between the epigastric artery and Poupart's ligament; then carried obliquely through the abdominal ring, gradually proceeding downwards to the inferior part of the scrotum. When a protrusion of peritoneum takes place, which passes before the spermatic cord, it must lie between the cord and fascia—the fascia covering it on the outside, and the spermatic cord being behind it. The hernial sac may be considered as entirely surrounded by a continuation of the fascia; also the spermatic vessels surround it at the same time. A hernial sac will be about two inches in length from the abdominal ring upwards, before you arrive at the cavity of the abdomen. The orifice of the sac, properly speaking, is not situated within the ring, but two inches above it, obliquely, which it is of importance to attend to, both in applying the truss and in the operation. Besides, it is erroneously described in all books as being situated at the orifice of the ring: this has occasioned a very improper manner of treatment in applying the truss, and a very

defective mode of performing the operation. In many instances of reducible scrotal hernia, to return the contents into the cavity of the abdomen, nothing more is necessary than a truss, with a pad properly applied to the orifice of the sac; if you compress the sides of the sac at the orifice, none of the contents of the abdomen can descend into the sac; if you make pressure below the orifice of the sac, a part of the intestines will still be protruded, it being open at the orifice, though closed below. A patient may be cured by the long-continued use of a truss properly applied, because it is gradually diminishing the opening in size, and will produce such a thickening, as well as diminution of diameter, that at length nothing will descend: there have been instances where it has been so contracted as only to admit of a probe, and, not unfrequently, it is entirely closed: though only considered as a palliative remedy, yet if long continued and properly applied, it is often a radical cure. A year is to be considered as a short time, and should not be depended upon. The truss should be continued for a considerable length of time after the patient is apparently well, as there may be still some opening left large enough to receive a small portion of intestine from some very violent effort, and when so narrow as to receive a small portion of intestine, it may produce inflammation, and all the symptoms of strangulated hernia.

When union has taken place of the superior part of the sac, and a part of it remains open below, a tumor may form there afterwards, from an accumulation of fluid; a hydrocele may form there, from the patient becoming dropsical; this has now and then happened after a patient has got well. It may be treated as the hydrocele of the *tunica vaginalis testis*. Also where a patient has been cured of a hernia by a truss, a second hernia may be produced at the same part by the formation of a second hernial sac, which he will be more subject to if the hernia of which he had been cured was large; for there is a dilatation of the abdominal ring, which remains afterwards larger and weaker than before, and a protrusion will be more likely to happen. The tendinous fibres are inelastic, and will sooner tear than stretch, yet, being a living part, they gradually undergo a change, and become elongated; hence the ring is sometimes three or four times larger than common. The bone likewise undergoes a change in its form, from the continued pressure.

When a hernia is irreducible, whether *enterocele* or *entero-epiplocele*, all that we can do is to direct the patient to wear a bag truss to support the scrotum, and prevent

a further increase of it. If an irreducible *epiplocele*, we may apply a common truss, if the spring is not very strong, which will be attended with this advantage, that it will produce adhesion between the sides of the hernial sac and omentum, preventing further protrusion of it, and any probability of intestine descending: he will be so far cured as to prevent further protrusion.

We ought not readily to give up a hernia as irreducible; for there are some which, by proper management, may be brought to a reducible state, as when it happens from an alteration of figure only, and not from adhesion, as when a patient has had an *epiplocele* for some time, he finds that, from being capable of returning it for some months past, he has not been able to reduce it as before. If there has been no pain or inflammation in the part, we may conclude there is merely an alteration of figure. As this arises from an additional deposit of fat, that may be removed by reducing the constitution of the patient by a spare diet, continued for some time, moderate evacuations, and what will still further contribute to it, keeping the patient in bed for a fortnight or three weeks on a spare diet, purged every third day, in which time he will become emaciated, a very rapid absorption of fat will take place, and relaxation of the part favourable for reduction will be likely to succeed. When replaced, a truss should be carefully applied, and well retained in its proper situation, to prevent any further protrusion.

When a scrotal hernia has become strangulated, the first attempt should be for its reduction, which will be most effectual in taking off the inflammation. The patient should be placed in a horizontal position, or nearly so, as lying on the back, only raising the pelvis a little above the chest by pillows: the leg of that side being raised towards the pelvis relaxes the muscles, and takes off the pressure of the fascia. While the patient is in this situation you grasp the tumor, and with the other hand (with the finger and thumb) you grasp the hernia above, near the ring, the intention of which is to diminish the size of the protrusion there: thus you gradually squeeze it through the ring. The pressure should be moderate, and uniform throughout. Violence might increase the inflammation, or produce a rupture of the intestines, which would be fatal. Though moderate, it should be continued for a considerable time. Moderate pressure for a long time, together with the peristaltic motion of the intestines, will favour their extricating themselves, so that frequently of a sudden they are felt going

inward, which is known by a guggling sensation. The remaining portion is soon reduced. This should be done with great caution and perseverance. You should not give up an irreducible hernia because the parts are not giving way. If you should fail in the first attempt, you are then to favour the abatement of inflammation by bleeding largely; if attended with syncope, it is then a favourable opportunity for again attempting the reduction. Next the warm bath should be used, which is frequently attended with very good effects, almost immediately alleviating the pain and diminishing the force of the circulation; and by keeping the patient there for a considerable time faintness is produced, which is another fair opportunity for reduction. If these should fail we are advised to give purging medicines by the mouth, to stimulate the intestines: this I believe to be prejudicial, as the intestines are in greater action than natural. By stimulating them the sickness of the patient is increased. Often, when remaining at rest and free from nausea, the taking any thing into the stomach excites the nausea, thereby favouring the return of the intestine into the sac instead of the abdomen; hence all medicines by the mouth are prejudicial, excepting opium. The abatement of the peristaltic motion will be in some degree rather favourable than otherwise, as it will retard the progress of inflammation. Clysters may be given with considerable advantage, sometimes as a fomentation to the part, or as a stimulus; or, what is more effectual, is a narcotic clyster, as tobacco smoke, or *infus. nicotianæ*, ʒss. ad ℥j., which I have frequently found successful. When given in the form of clysters it produces considerable abatement of pulse, and general relaxation is often the consequence, during which time the hernia will frequently return. I have known these succeed, without any pressure, when every thing else has been tried and failed.

External applications to the part, I believe, are of little service. Two kinds are recommended, warm and cold. Warm applications, in the form of fomentations, which may have some effect in abating the inflammation, are supposed by some to produce an expansion of the air contained in the intestines. But it is now known by the experiments of Dr. G. Fordyce, that great heat applied to external parts hardly produces any alteration in the internal parts; therefore the application of poultices or fomentations produces no alteration in the size of the intestines, but as a sedative may sometimes abate the inflammation.

Cold applications have been used with a view of diminishing the bulk of parts, as

the volume of air; but this, as before said, produces no variation in the internal parts. As cold is a very powerful sedative, so far it may be useful. Solutions of *Sal. Ammon. Crud.*, or any other salt (while the salt is in a state of solution it increases the coldness of the water), will be a good application. If snow or ice can be procured, it will be still better. I have known ice applied to a hernia till it has absolutely froze the skin; however, the hernia still remained unreduced, yet it evidently stopped the symptoms, and even the inflammation. It was determined then to perform the operation; the incision was about to be begun, when a guggling noise was heard, and it was found the intestine had passed up. In this case I make no doubt that mortification would have taken place before many hours. It is supposed by some, in returning a hernia, that the sac is often returned into the cavity of the abdomen; this, I believe, is very rare, for generally the sac, after it is formed, soon takes on adhesions with the surrounding parts.

CLINICAL LECTURE

ON THE

TREATMENT OF DISEASES OF THE HIP-JOINT,

*Delivered at St. George's Hospital,
Nov. 14, 1837,*

BY SIR BENJAMIN C. BRODIE, BART.

LECTURE III.

IN the last lecture I began the subject of the treatment of diseases of the hip-joint, and I explained to you that without reference to what the disease is, there is one kind of treatment applicable to all these cases—I may say, indeed, applicable to all cases of diseased joints—namely, the taking away of the function of the joint, and keeping it in a state of complete immobility. I repeat this observation, at the risk of being tedious, because it is a rule of the first importance. This is the principal improvement in the local treatment of diseased joints made of late years. Formerly, patients were allowed to use their limbs, and now they are not allowed to do so, the bones being kept in a state of repose, with as much care as in a case of fracture.

Then I explained to you that in cases of diseased hip there are different ways of attaining this object; that sometimes you may apply a leathern splint, something like what we apply to the ankle or the knee; that at other times we put on a great quantity of plaster and bandage, in alternate layers; and that in

other cases it is quite sufficient to keep the patient lying on his back on one of Mr. Earle's invalid bedsteads.

In cases of inflammation of the synovial membrane, you are to employ that treatment which you would employ in other cases of inflammation. When the inflammation is very intense, it may be necessary to take away blood from the arm; but it is generally sufficient to bleed locally, by cupping on the nates, or by applying leeches to the groin; or you may cup on the nates first, and then apply leeches to the groin afterwards. The patient should have his bowels kept open; and if there be any febrile excitement of the system, he may require antimony or some other diaphoretic medicine. However, in general, inflammation of the synovial membrane of the hip is of a chronic character, not disturbing the constitution, nor requiring remedies of this last-mentioned kind.

As the inflammation recedes, you may apply blisters in the neighbourhood of the joint—on the nates in the groin also. The skin of the groin is nearer to the hip-joint than the skin of the nates, and blisters and other local applications may be made in the groin with very great advantage.

Occasionally other remedies may be employed with advantage. In cases of inflammation of the synovial membrane of the hip, as well as in cases of this disease when it occurs elsewhere, especially in private practice, among the more affluent classes of society, who live luxuriously, and do not take sufficient exercise, or in those who expend their nervous energy in intellectual pursuits, and have not sufficient left for the physical part of the system, you will find it connected with a gouty diathesis. The patient complains of acid generated in the stomach after his meals; of heartburn; he is flatulent; he rests uncomfortably at night; he has flying pains about him besides those of the hip; the urine which is made 3 or 4 hours after dinner is voided clear, but when it cools it deposits a great quantity of sediment; sometimes there is a pink sediment, which stains the chamber utensil, making it look like what is called a *pink saucer*; and sometimes there is a yellow sediment. These sediments are composed chiefly of lithate of ammonia, and they indicate a tendency to acidity in the stomach, and to gout in the system.

When inflammation of the synovial membrane of the hip occurs under these circumstances, in addition to the treatment, which I have already mentioned, you may employ other remedies. Occasionally give an active purgative,

and keep the bowels gently open in the meantime. About 3 or 4 hours after breakfast, and 3 or 4 hours after dinner, let the patient take a dose of magnesia, or potass, or soda, to neutralize the acid which there is then in the stomach. I do not think that medical men in general, when they prescribe magnesia and the alkalies, are sufficiently careful to tell their patient at what particular times to take them. They are to be taken when there is acid in the stomach to be neutralized. There is none in the morning before breakfast; and these alkalies taken in the morning, at any rate do no good, and probably are injurious. There is the greatest quantity of acid in the stomach about 4 hours after a meal, and subsequently to that period it has begun to get into the system, and then produces the secretion of lithic acid by the kidneys. Your object is to neutralize the acid before it passes into the circulation, and you must do that when the acid is in the stomach. A patient told me the other day, who had inflammation of the synovial membrane of the knee, accompanied with this pink deposit, that he had observed that if he took the alkali 3 or 4 hours after a meal, there was no pink deposit; but that if he took it 5 or 6 hours afterwards the deposit appeared as usual. Another remedy, very generally useful in these cases, is *colchicum*. If the pain in the affected joint be very severe, and it is connected with that peculiar state of the system which I have just mentioned, the tongue being at the same time tolerably clean, you may give half a drachm of *vinum colchici* two or three times daily, for a few days, till it begins to create nausea, or to disturb the bowels. But in less urgent cases I prefer giving it in a milder form. You may exhibit 2 or 3 grains of *Ext. Aet. Colchici* every night, combined with a small dose of the compound extract of colocynth. This must be taken for ten or twelve successive nights. Sometimes the *colchicum* produces yellow stools, shewing that it stops the secretion of bile; and to counteract this tendency, you should add 1 or 2 grains of blue pill to each of the pills.

There are other cases of inflammation of the synovial membrane of the hip, connected not properly with a gouty tendency, but with rheumatism, and where the patient may derive great benefit from taking some mercurial preparation—Plummer's pill, or calomel and opium, for example; and the latter may be exhibited in severe cases, so as to affect the gums.

Inflammation of the synovial membrane of the hip, when it has any sort of attention paid to it, very seldom goes

on to any ill consequences. In a very few rare cases, as I have already explained to you, it terminates in what has been called spontaneous luxation of the hip. It seldom terminates in absolute ankylosis, but very frequently there is a great degree of stiffness of the joint for a considerable time afterwards. Ankylosis, however, occurs occasionally. A patient was admitted into this hospital, who was observed to have something odd in his gait as he walked, but he did not complain of his lower limb at all, and therefore nobody took much notice of it. He had some pneumonic disease, of which he died under the care of the physician; and on examining the body after death, we found that there was complete ankylosis of one hip, but not bony ankylosis. There were the remains of the capsular ligament and synovial membrane closely adhering to the parts below: there was a thin layer of cartilage between the bones, but merely a single layer, as if the cartilage of the head of the femur and the acetabulum had become united to each other. I do not know how the circumstances of this case can be explained, except by supposing that it was the result of inflammation of the synovial membrane. Had the ankylosis been the consequence of ulceration of the cartilage, the cartilage would of course have disappeared.

The treatment of those cases, which unfortunately are of such frequent occurrence, of serofulous disease of the hip-joint in children, having its origin in the bones, and then extending from them to the cartilages and other structures, is very simple. If you are called to a child in the early stage of the disease, when he limps and complains a little of pain, or perhaps does not complain of pain at all, the local treatment should be simply negative. *Keep the hip-joint in a state of perfect immobility*, which you may accomplish by a leather splint, by plaster and bandages, or merely by the invalid bedstead. I repeat that *this is all the local treatment which the disease requires, if you are called to the patient in the first instance*. I remember the time when in these cases we were in the habit of applying leeches, blisters, and issues. I am satisfied, from all I have seen of the two kinds of practice, that the abstraction of blood and the application of counter-irritants, not only do no good, but that on the contrary, by weakening and worrying the patient, they sometimes do great harm. In my own practice I have been much more successful since I laid aside all these painful remedies, and relied merely on perfect rest.

Perfect rest will do a great deal towards stopping the progress of the sero-

fulous disease in the joints; that is, when it has taken place in the bones, it will prevent the ulceration of the cartilages; if the cartilages are ulcerated, it will prevent the ulceration extending further; and if matter is not yet formed, it will retard, or even prevent, its formation. Yet after all, this negative treatment does not strike at the root of the disease, which is not in the part in which the disease shews itself, but in the patient's constitution. You may well suppose, that mere rest will not correct a serofulous constitution; and that for this purpose you must have recourse to other means.

To lay down any rule of constitutional treatment, such as will be applicable to all cases, is not possible; you must exercise your discretion in each particular instance, and I can only undertake to give you some general notions as to the plans which you should pursue.

In the first place, then, you should take care that the digestive organs are properly attended to: if the bowels are confined, purgatives should be administered according to circumstances. If there be a deficiency of bile in the evacuations, a little mercury should be carefully exhibited, to correct the faulty secretion. The child will then require some kind of tonic. Various tonics may be employed with advantage, some in one case, some in another; but the remedy in which my experience leads me to place the greatest confidence is some preparation of iron; and in children I find nothing answer better than steel wine. I do not mean the modern steel wine, which contains scarcely any steel, but the old wine, made according to the old Pharmacopœia, and which is almost of a black colour. There is no occasion for giving it in large doses. To children of 3 or 4 years of age, give a drachm twice daily; if the child be a little older, give two drachms; and to one approaching the age of puberty, you may give three or four drachms for a dose. It is not important in these cases that the steel should be taken in a large quantity, but it is important that it should be continued, with occasional intermissions, for a great length of time. The best cures that I have seen, not only in cases where the hip-joint was affected with the serofulous disease, but also where the disease was situated in the knee and other joints, and even the spine, have been in those cases in which steel has been given, off and on, for a great length of time—for 3 or 4 years, or even longer. I give it for a month, then stop it for ten days; I then give it for another month, then stop it for ten days again, and so on, combining purgatives with it, according to circum-

stances. This system, in four cases out of five, agrees with the child exceedingly well. You will not see any marked improvement at the end of the first month, but you will at the expiration of six or twelve months. I could tell you of families where the most delicate of the children have by the long-continued use of steel, in this manner became the strongest of the whole set. I do not think that steel in these cases is, under ordinary circumstances, given to a sufficient extent. The parents get impatient of giving the child medicine every day, as well as of the expense of medical or surgical attendance, and the medical man himself naturally becomes tired of his attendance under these circumstances. There is no perceptible improvement from day to day, and it is difficult to command confidence where the change is not visible perhaps for six months, and to induce the patient or the parents to persevere in the use of this, or any other remedy for so long a time.

But such perseverance is really what is required, and it is necessary to explain it to the parents in the first instance. Of course I am now supposing that steel agrees with the child; but there are some who cannot take it except in small doses; and there are others who cannot take it at all without its producing headache, making them costive, heated, and feverish. Other tonics may then be exhibited, such as quinine, some of the bitters, or what, perhaps, is better still, the alkaline infusion of sarsaparilla. The latter is a very excellent and useful preparation, and I will give you a formula for preparing it, as it is not in the *Pharmacopœia*:—To make a pint of the infusion, you take two ounces of the root of Jamaica sarsaparilla, cut and bruised; then you add two drachms of liquorice root, to cover the taste of the sarsaparilla; to this you add two drachms of the *liquor potasse*, and about 18 ounces of boiling distilled water; macerate the whole in a close vessel for about 20 hours; strain off the liquor, and you may give the patient, according to his age, from 4 to 6 or 8 ounces of this infusion daily.

But there is still another method of improving the child's constitution: let him live in the fresh air as much as possible. All that I have seen leads me to believe that nothing tends more than this to strengthen a delicate constitution: of course I mean, not that the child should be exposed to cold, or wet, or night air, but that he should pass his time out of doors in fine and temperate weather. In the summer his couch may be placed in the garden, and he may remain there during a great part of the day; if it can be managed that he should reside at the seaside, it will be so much the better;—I say

reside, for as to his being taken for a month or six weeks to a sea-bathing place, the benefit which he will derive from it is not such as to compensate the mischief which may arise from the journey, especially if it be to a distant place.

The period during which it is necessary to keep the patient in the recumbent posture, must vary very much in different cases; in some cases, three or six months may be all that is wanting; in others, the patient must perhaps be kept lying down for twelve months; and where the joint has been destroyed by an abscess, and the bones have become displaced, even a much longer period may be necessary: but I shall speak of these last cases presently.

The treatment of those cases in which the cartilage of the hip ulcerates, independently of that scrofulous disease of the bones which I have just described, and which we call, by way of distinction, cases of primary ulceration of the cartilage, (though it may sometimes be originally disease of the surface of the bone, and sometimes of the cartilage itself—two orders of cases which I cannot pretend to distinguish in practice) in many respects resembles the treatment of scrofulous affection of the hip-joint. The patient must be kept in the same state of perfect immobility; but he does not in general require the same treatment otherwise. Very often he will derive much benefit from a course of sarsaparilla; at other times he will derive still greater benefit from being put for a certain time under the influence of mercury. In many of these cases he will derive benefit from the employment of what we call *counter-irritation*. Although I do not recommend the employment of blisters and caustic issues in other cases of disease of the hip-joint, yet I do recommend them here. You may apply a blister to the nates, or to the groin, or you may make a caustic issue behind the trochanter large enough to hold 12 or 15 peas. Usually, however, I keep the issue open, not by peas, but by rubbing the surface of it about once in a week with the caustic potass, dressing it in the meantime with the savine cerate. You may distinguish where you ought and where you ought not to employ these means with sufficient accuracy; thus, if the disease has not been marked by much pain previous to the formation of matter—if there has been limping for a long time with scarcely any suffering—you may conclude that the case is one of scrofulous disease, and that counter-irritations are unnecessary; but if the disease has throughout its whole course been accompanied by pain, becoming gradually more severe, then you may conclude that it is not one of those scrofulous cases, and that counter-irritation will be bene-

ficial. I speak of pain, observe, previously to the formation of matter; for when matter is formed in the joint, there is severe pain in all cases. Where the pain is very severe, and is not relieved by a caustic issue behind the great trochanter, you will sometimes afford great relief by making a seton in the groin, in the fore part of the joint. I suppose that the pain in part depends on irritation communicated to the anterior crural and obturator nerves, and that this will explain the relief obtained from a seton made in their vicinity.

I have hitherto said nothing regarding the treatment of abscess connected with the hip-joint, having reserved my observations on this subject to the last, because the treatment of abscess of the hip is pretty much the same under all circumstances—whether the disease has begun in the synovial membrane, the bones, or the cartilages. Whenever you find that the patient complains of a great aggravation of his former symptoms, when the pain becomes intolerable, the limb starting at night, and the pulse becoming increased in frequency, you may always suspect that matter is forming in the joint, and that the acetabulum is becoming filled up with matter and lymph. You may, under these circumstances, employ fomentations, which may help the patient a little, but not much. If the pain be excessive, you must give opium, though I am not desirous of giving it without ample reason for doing so, on account of the ill effect which it produces afterwards on the digestive organs. By and by the abscess presents itself externally, and this is almost invariably followed by a shortening of the limb, produced in one or other of the ways which I mentioned formerly.

When the abscess presents itself, you will feel it, and you may even see it; but if it is yet deep-seated, I would not advise you to open it, because, first (especially in the cases of very delicate children), there may be a loss of blood which the patient cannot afford, and, secondly, because under these circumstances the wound will heal directly, and the matter will become pent up as it was before. An exception, however, to this rule may be made in those cases in which you find an abscess burrowing under the fascia, instead of coming forward to the surface, and then it may be right to make an opening through the fascia, to prevent the destruction of the parts below.

Different methods have been recommended for opening these abscesses; but I shall not occupy your time by a critical discussion as to their respective merits. Some have advised an oblique or valvular opening, others a direct opening; some

have advised us to keep the orifice open, and others to heal it; some have advocated the use of the lancet, others of the caustic potass. I shall merely tell you what, according to my experience, is the best mode of managing these cases. The patient having been kept for a considerable time in the recumbent posture, when the time arrives at which you think proper to open the abscess, do it with an abscess lancet, or double-edged scalpel, and make a large opening, so that the matter may run out freely of itself; and that there may be no obstruction to its discharge from the opening becoming blocked up by curdly matter or flakes of lymph. But having done this, be satisfied that you have done all you ought to do. *Never squeeze and compress the parts to force out the matter; never move the limb for the same purpose, nor allow others to do so.* If you attempt to squeeze out the matter you bring on inflammation in the cyst of the abscess,—you induce bleeding from the small vessels on its inner surface—the blood collected in the cyst of the abscess mixes with the pus, and becoming putrid, produces great constitutional disturbance, taking on the character of typhus fever. It is said that bad symptoms often come on on opening an abscess; but I believe that for the most part it is not the opening of the abscess, but the rough hand of the surgeon in trying to squeeze out all the contents of the abscess, that does the mischief.

Then, are you to bring the edges of the wound together, and heal it, or not? My own practice is to apply a poultice, and to leave the wound to take its own course. On the whole, I would rather that the wound did not heal; but I do not usually endeavour to prevent it healing by introducing lint into it, lest this irritate the inner surface of the abscess, and excite a mischievous inflammation in it. If it does not heal, it is so much the better; the matter continues to flow out, and the cyst of the abscess gradually contracts. If the wound does heal, the matter will of course be again collected, and you must make another opening. If the abscess should present itself in two or three different places, do not be satisfied with one opening, but make an opening wherever it presents itself, as otherwise there can be no proper evacuation of its contents.

In the majority of cases in which abscess has formed, the cartilage is destroyed, the bones are carious, the synovial membrane and ligaments have in great measure disappeared, so that there is really no joint left. The case may now be compared to one of compound fracture, and you are to treat it just in the same manner, by keeping the limb in a state of perfect immobility, and

taking care that the matter should flow out as fast as it is generated; but it may take a long time for this abscess to heal—months always, and even years in some cases. But ankylosis will be going on all the time, though the period of its completion varies. In the serofulous disease of the bone, it takes a long time for bony ankylosis to be effected. If you examine the limb many years afterwards, you will often find that the ankylosis is not by bone, but by a sort of ligament. But when the cartilages are ulcerated independently of the serofulous disease of the bones, the bones being in a tolerably healthy state, bony ankylosis takes place at a much earlier period.

As soon as you find that the thigh and the pelvis move completely together, there being no perceptible motion of the joint, you may be satisfied that there is sufficient ankylosis to enable you to allow the patient to begin to take exercise on crutches.

In all cases the patient experiences great pain at the time that the head of the thigh-bone is being pushed out of the socket, or if the head is destroyed, when the neck of the femur is drawn up and lodged above the acetabulum; and this pulling up of the head or the neck of the thigh-bone is always followed by great and permanent distortion of the limb. Can you do any thing to prevent those sufferings, and the subsequent distortion? The patient suffers because the head or the neck of the femur is leaving its own place, and getting into new parts which are not intended to have the rough bone in contact with them. I have in some instances endeavoured to prevent this by mechanical means,—that is, by the application of an extending force to counteract the action of the muscles: and a very slight force is sufficient for this purpose. It is astonishing what comfort I have known this to give the patient in some instances. As soon as you have reason to think that the limb has begun to shorten, you may begin to make a gentle extension below, so as to counteract the action of the muscles above; and experience shews that this may be done with the most perfect safety.

As to the mode of accomplishing this object, it is sufficiently simple. The patient is to be placed on his back, on the treble-inclined plane of an invalid bedstead, with his shoulders and his thighs a little elevated. An upright piece of wood is fixed to the foot of the bed, and in this upright piece of wood there is a pulley, which pulley is just in a line with the thigh-bone. There is a bandage round the patient's thigh above the knee, a string extends from each side of the bandage, and joins another string which passes over the

pulley. At the further extremity of this last string there is a very light weight attached—a few ounces of shot or some copper penny pieces put into a basket are sufficient in the case of a child. You often require a great extending force to counteract the powerful action of the muscles in reducing a dislocation, but a very slight force, constantly acting, is sufficient to counteract the weak action of the muscles in these cases. My experience of this practice leads me to believe that by the adoption of it you may prevent a great deal of the pain and suffering belonging to these cases, while at the same time this method has a tendency to lessen very much the ultimate distortion of the limb.

I have spoken to you in these lectures of the ordinary diseases of the hip-joint; and it is not my intention to enter into the history of the diseases of more rare occurrence. I have known instances of scirrhus disease and fungus hæmatodes of the hip; and then there are hysterical affections which simulate the symptoms of other diseases. I gave lectures upon the latter of these subjects a year ago, and these have since been published. A knowledge of these hysterical affections is of great importance, in order that you may not be in danger of confounding them in practice with cases of actual local disease; but under the circumstances which I have just mentioned, I feel that it is quite unnecessary for me to enter into the consideration of them at present.

CASE OF FITS WITH VERY SLOW PULSE.

By JOHN R. GIBSON, Esq.

[Concluded from p. 126.]

THE pathological condition which existed in the case above detailed, and which gave rise to the fits, was involved in great obscurity. It was evident there was great interruption to the heart's action; that this interruption was always sudden, and more or less prolonged; and if we may be allowed to reason on the ground of probability, in the place of proof, it was also evident that the fits were dependent on this interruption to the action of the heart; for, after a due lapse of time from the last stroke of the heart, the symptoms ushering in a fit immediately commenced, and were either continued and augmented to the development of a true fit, if the heart did not quickly act; or, if it did, they

were diminished, and perhaps entirely subdued. This condition was so true and so constant, that no doubt at all could exist upon the question of how far the fits were determined and regulated by the action of the heart, inasmuch as when the interval was short there was no perfect fit, merely the pallor without loss of sensibility, &c.; but if the interval were longer, the symptoms constituting a true fit were produced, and became either violent or slight, just in proportion to the length or shortness of the interval. Now such was the condition which observation taught us: the question, however, arose—upon what this interruption of the heart's action depended? It was vain to speculate upon such a point from the evidence which was then before us. It was suspected whether ossification of the coronary arteries did not exist, and how far such a condition would determine such symptoms. It was also conjectured how far an obstruction to any nervous supply would act; but supposing any physical obstacle existed to the proper supply of nervous energy, such obstacle could not be permanent, for the history of the case could not warrant such a conclusion: if, then, merely temporary or functional, through what organ, or in what way?

When I first saw him the pulse was beating steadily, without the least irregularity or intermission, at the rate of 22 in the minute. He had partaken of salmon at dinner, and had vomited, which was a very rare occurrence. There was some nausea, and a degree of fulness about the abdomen. The surface was bedewed with a cold clammy sweat, and I was certainly greatly disposed to regard these fits (I had not then seen one) as connected in a great degree with a disordered condition of the alimentary canal, and ordered accordingly the medicine mentioned in the report, with a view of clearing out the bowels, relieving any acidity which might exist, and arousing the circulation. It had the effect of freely moving the bowel; but the circulation, instead of being aroused, was slower, being but 18 in the minute, and with the additional symptoms of irregularity and intermission. The evacuations had been very offensive, and I determined on continuing the medicine, but reducing the dose of the aperient, and increasing the dose of the stimulant. I then exa-

mined the heart with the stethoscope, but could make out nothing satisfactorily. There was no unnatural sound, but the proper sounds could not be distinguished; the impulse could be felt, but nothing more was distinct. In the afternoon I saw him again; the fits had continued with very little intermission since the morning, sometimes being slight, at other times more violent. During my visit he had several in quick succession; and from the great congestion which they produced, I determined on taking away a few ounces of blood. While the blood was flowing he had two or three fits, and it did not appear to afford any benefit. In the evening I saw him again, and a medical friend accompanied me. During our visit he had no fit. My friend suggested the application of a blister to the nape of the neck, and some assafoetida mixture in combination with some aromatic spirits of ammonia. He passed the night pretty free from fits, and had sleep. About nine this morning the fits returned. The surface was warmer than on the preceding day, but there was no improvement in the circulation. Some good beef-tea was to be given him during the day, and occasionally a little gin and water, which he preferred to any other spirit, and some beer or wine if he desired either. The fits continued through this day. In the afternoon I ordered a stimulating draught to be given every ten minutes or quarter of an hour, but it produced no good effect. On this evening Dr. Roots saw him—ordered some caudle to be given him, and the stimulating medicine, which, if any thing were calculated to arouse the heart's action, these were; but they failed; and the next morning, after having struggled through many a long and serious fit, and having hitherto gained the mastery, he was now compelled to yield to their strength, and yielded with his life.

To the *post-mortem* examination we must resort for an elucidation of these very anomalous symptoms. We find no disease about the heart or its own vessels which would in any way account for the sudden cessation of its action. Nor do we find any affection of any distant organ which would at all aid us in our inquiries; but we do find the aorta dilated, ossified, and otherwise diseased; and it is to this, and this chiefly, we must look for a solution of

our difficulty. The dilated state in which we found the aorta of this subject, can, I conceive, only be produced by some obstruction to the flow of blood in its course; and whether the obstruction be far or near from the commencement of the vessel, the greatest dilatation will be found where the force of the blood, as derived from the action of the heart, is greatest—where its muscular force is more directly expended. The amount of dilatation will, of course, depend not only on the degree of obstruction, but on the situation in which the obstruction exists; inasmuch as when the obstruction is low down, and below the principal vessels which are given off from the main trunk, these will afford a large amount of blood to flow into them, and, as such, render the necessity of distension of the main trunk much less called for; but when the obstruction is high up, and above the principal branches, the blood propelled into the artery, not having the advantage of the collateral vessels, must necessarily be retarded in its course, and cause a proportional dilatation. The situation, however, at which the greatest dilatation would be found, would be that part of the aorta where the greatest muscular force of the heart is expended, the blood already in the vessel not being permitted to escape. Now this part would be the arch of the aorta, and it was here where the greatest dilatation was found. It is not necessary, I conceive, to insist upon the necessity of there being some obstructing cause to the flow of blood through the vessel, in order to produce dilatation, under a healthy condition of the heart; for the flow of blood through the vessel under a natural condition of parts would be so uninterrupted and free, that to suppose a dilatation would be seeking to establish a provision which nature has neither made nor intended. To meet, however, an argument which might be raised, that the aorta in the present case was diseased, and as such its elastic properties greatly overcome—that it would therefore yield to the continued impulse of the heart, producing dilatation, let it be borne in mind that, although the artery was diseased, and its elastic powers greatly lost, the artery at its commencement was almost free from any apparently diseased condition; that this commenced below the arch of the aorta, and increased as we proceeded onwards. It is, however,

useless, I conceive, to meet such argument, as it is quite inapplicable to the present case, inasmuch as an obstructing cause does exist—the ossified state of the aorta at its division into the two iliaes. Moreover, the obstructing cause does not consist simply of the ossified state of the vessels, but the situation in which the ossification is found. It is at the inner and posterior part of each vessel, from their very commencement to some little distance along them. Now it must be, I think, apparent that this situation, of all others, would be most favourable to any impediment which might be offered to the flow of blood into them. From the direction of the aorta, the very course the blood must take in entering the two iliaes would be to strike against the inner side of each vessel; and if these, instead of presenting a smooth surface possessing elastic properties, adapted to the free circulation of the blood through them, present a rough, projecting, and unyielding surface, ill adapted to the mere transit of any fluid, and altogether so in aiding the motion it has already obtained, it will hence be manifest that the arrest to the flow of blood must have been by no means slight, but equal, and more than equal, to produce the dilatation on the upper part of the aorta.

A further reason, although not so forcible a one, may yet be assigned for a sluggish flow of blood through the aorta. It will be remembered the aorta presented those yellowish white spots very commonly observed, and which M. Bizot considers as terminating sometimes in ulcerative softening, at others as forming the nidus for the deposit of ossific matter. Now all these several conditions existed; the spots before referred to were numerous, in some places forming patches. There was one spot about the size of a sixpenny piece, in which ulceration had taken place; and in another, ossification. Such a condition of the aorta, although not incompatible with the performance of its function, must have rendered its discharge very imperfect, by being but little able to impart fresh vigour to the flow of blood, and in some places to offer actual impediment to it.

Another point fully worthy of comment has yet to be noticed: it is the ossified condition of the branches of the internal iliac artery, forming a still further obstructing cause. Here our in-

vestigations into the state of the arteries terminated. We may now enter the boundless regions of conjecture; but without entertaining any extravagant notions, or unlawfully exercising our liberty, we may fairly infer, that had our investigations proceeded further, arteries, perhaps many arteries, unavoidably unexplored, would also have been found in the same diseased condition. The sluggish state of the circulation is also supported by another fact, that his extremities were always cold, and so cold, I have been informed by his daughter, have his hands been on one of the hottest days this summer, that it almost produced a chill in holding one. The slow state of the circulation would moreover be encouraged, not merely by the slow action of the heart, but by the inertia of the whole circulating mass being required to be overcome at each successive impulse of the heart; for by the great length of the interval between each contraction of the heart, the impetus the blood had gained would be almost lost. If the circulation had approached at all near its ordinary rapidity, this argument would really be quite insignificant; but when we find the heart contracting only two-and-twenty times in a minute, and even less than this, the interval is so appreciable, that the motion which the blood received must be almost lost, especially when we admit the several obstructing causes; and instead of its muscular force being expended in accelerating a motion already existing, a large amount of it must be spent in producing this motion.

With the evidence which is now before us, may we not proceed to offer an explanation of those very singular fits? Now what were the features by which they were recognized? If slight, merely a pallor of countenance, without loss of sensation, volition, &c., quickly followed by a slight transient blush, and all was again natural. But upon examining the heart at the time at which you first discovered this pallor, you would find it had ceased to act; but the moment it again acted, the pallor would immediately subside, and give place to a blush. If the fit were more complete, the pallor would continue, a ghastly expression of countenance would appear, the eyes would be upverted, convulsive twitchings would take place, total loss of sensation, volition, &c. &c. Upon

the heart again acting, a sudden blush took place, extending to almost every part of the surface, especially the head, face, and neck; sensibility then quickly returned, and all was as before. Now these symptoms manifested themselves just in proportion to the suspension of the heart's action, and were prolonged and regulated by the duration of that suspension. But although the heart ceased to act for so long a period, or, if it acted, acted but feebly, this feature was always observable on the subsidence of the fits—that the heart acted steadily for about five beats at the rate of 60 in the minute, and then returned to its ordinary slow state. Now we have seen an obstructing cause existed to the flow of blood through the aorta; that this obstruction was increased by an ossified state of the branches of the left internal iliac; that it was increased by the diseased condition of the aorta; that the inertia of the circulating fluid favoured this obstruction; and moreover, that the dilated state of the aorta, when once established, would aid rather than relieve this obstruction, inasmuch as in proportion to the amount of dilatation would the natural elasticity of the artery be overcome. Such being the condition of parts, does it not most satisfactorily explain the occurrence of the symptoms already detailed? The artery, from obstruction and deprivation of its proper powers, was unable to send forth the blood propelled into it at each impulse of the heart; the consequence of this would be, an almost temporary arrest to the circulation through it; or if not amounting to an actual arrest, the circulation would be so slow as to present a physical obstacle to the further entry of blood; and as such the heart could not act. This was precisely the condition which did exist; the heart did not act, and for it to have attempted to act would have been useless, until the vessel was in some measure relieved of its contents. When, however, this object had been gained, and the urgent necessity of its action to life demanded its action, it again acted; and now we see, not the sluggish action which was observed at other times, but an ordinarily rapid one for a few beats, until it was again, as it were, warned by the distended state of the aorta that its efforts would be useless, and the same sluggish action was again produced. In this case can we not observe how beauti-

fully those organs immediately concerned in the production of these phenomena have adapted themselves to the new circumstances under which they have been required to act. When the obstruction existed, the blood must necessarily have been thrown back upon the heart. To provide against this evil, we find the artery dilating, in order to accommodate a larger amount of blood. When this was effected, the heart, instead of acting with its accustomed frequency, became slow in its action, the pulse being but 22 in the minute, and afterwards 16. We find, moreover, the collateral vessels dilating, for, as stated in the report, the hepatic veins were unusually large, and the arteries encircling the intestines were most clearly seen. Another organ must yet be noticed, to complete the chain of obstructing causes; I allude to the condition of the liver. From the structural change which nearly the whole of it had undergone, it is but fair to infer that the large amount of blood sent to it by the venaportæ, would not find so ready an escape as under a healthy condition of this organ. How long such a condition has existed is difficult to say, but I think it is most probable, from the sedentary habits the patient has led for the last few years, it has gradually been growing upon him, and was increasing. That this undoubtedly would form a further obstacle, inasmuch as the quantity of blood the mesenteric arteries, both large vessels, could have carried away, and thus have relieved the obstructions elsewhere existing, has been greatly lessened.

The causes which have been adduced might perhaps be thought insufficient to explain the very serious and at last fatal character which marked these fits; for when we remember arteries, and important arteries, are continually being tied, and even the aorta itself, without producing similar effects to those detailed, it should justly render us somewhat scrupulous in attaching so much importance to these causes, which, theoretically considered, would have much weight. But in taking a review of this case, and in contemplating the morbid states of the several organs, we find that the evidence in favour of our view has increased and accumulated; and although it would be highly unphilosophical, and most unsought for, to endeavour to attach a greater significance to

any one of the facts than it really deserves, yet, at the same time, it is but just to allow to each that amount of worth which it absolutely possesses, and also to consider the relative bearing one fact has upon another: for although any one taken singly might be justly considered as insignificant and unimportant, yet, when placed together, and estimated not only in their absolute strength but accumulated force, they have a higher claim upon our attention than at a *primâ facie* view they appeared to possess; like the scattered fragments of a noble edifice, each possessing but little beauty, and having no claim upon our notice; yet, when skillfully arranged, constitute a magnificent fabric, not only commanding our attention, but well meriting our praise. We see, then, obstruction existing, not merely at one part, but at many; we trace it in the aorta, its branches, and the vessels leading from these, until a circle of obstructing causes is almost formed. We see, moreover, at the time of death the heart is loaded, the aorta and its branches are unusually filled, and the returning veins in a highly engorged condition. Another fact would also, I think, favour the view which I have taken of this case, that the fits occurred more frequently on occasions of particular excitement, by which the heart would be stimulated to act, the aorta would be unduly filled, and by thus causing a suspension to its action a fit would be produced. It is also worthy of remark, that until the last few years, when the fits assumed a determined character, he was troubled with what he termed a swimming in his head: now was not this produced by a short interruption of the heart's action, insufficient to destroy sensation, volition, &c. but sufficient to interrupt the circulation in the brain?

A reasonable inquiry might here be made, why it was the cessation of the heart's action was so prolonged? for although the aorta might be so filled as to warn the heart against any futile attempt to pour forth a fresh quantity of blood, yet the blood must be flowing, and the engorgement of the vessel would be quickly relieved, or sufficiently so to have allowed the heart to act, before, in many instances, it made any attempt. The following explanation appears to me satisfactory:—The heart, although it possesses an irritability in

itself, by which it can act independent of any other organ or system, yet it is found to be greatly under the influence of the brain and nervous system. When the heart was compelled by necessity to withhold its efforts, and the necessary suspension was too long to be compatible with the performance of the functions of the brain, a state equivalent to fainting was produced; under such condition, the heart would not receive that supply of nervous energy necessary to its proper function, and the interval was therefore prolonged. Although a state equivalent to fainting was produced, yet the phenomena accompanying that state were very different to those attendant upon ordinary fainting. In fainting, the heart generally becomes gradually feeble in its action; in the present case there was sudden cessation of its action: in fainting, the respiration generally keeps pace with the feeble circulation, being sometimes scarcely perceptible, and accompanied with an occasional sigh. In the present case there was no correspondence between the respiration and circulation, for although the heart had ceased to act, the respiration was continued, and with increased quickness and labour. In fainting, the establishment of the circulation is gradual and progressive, but in the present case it was as sudden as it was interrupted. The condition of the lungs fully corroborates this account; for of all the parts which constitute the grand mechanism of the human body, none which underwent inspection was found free of an engorged condition but the lungs; and these, as I have stated in the report, were as perfect a specimen of healthy structure as could possibly have been selected.

But we cannot conclude without contemplating still further the adapting powers of nature to the various trying and perplexing circumstances which attend her operations. To suppose for a moment, in the present case, she had taken an opposite course to the one she has adopted—that instead of the slow action of the heart adapted to the escape of blood from the vessel, and the occasional interruption to this action to allow of an escape under an unnatural and over-distended state—the action of the heart had been rapid and vigorous, and without any cessation, quickening the motion of the blood, urging its escape through canals whose calibres

were lessened, whose coats were unyielding, and whose strength was unequal to support the rapid and vigorous strokes of so powerful an organ; such a condition might have been supported for a brief space of time, but it must quickly have terminated. The evil under the present condition was great, but it existed for several years, and life was prolonged to the not youthful term of 70. The evil under the opposite condition would have been greater, and the almost inevitable result must have been laceration of some important artery, bringing his existence to a rapid and fatal end.

This, then, is the view which I have ventured to offer upon this interesting case. The pathological condition neither suggests nor warrants, I conceive, any other; but it would afford me no small gratification if the phenomena which characterized this case could be explained in accordance with the morbid condition of the several organs by any other view. A point of physiological interest may yet, perhaps, not unfairly be deduced from it. It has long been a question among physiologists, whether the capillaries have the power of circulating the blood independent of the heart's action? and this question is, I believe, not yet determined. Now, in the long suspension of the heart's action in this case, did the blood circulate only by the impulse it received from the heart, or was it carried on by any power on the part of the capillary vessels?

MEDICAL EDUCATION.

To the Editor of the Medical Gazette.

SIR,

ONE part of your excellent editorial remarks on the best mode of conducting medical studies, contained in the *GAZETTE* of last Saturday, seems to have been written under an erroneous impression; and I therefore take the liberty of calling your attention to the subject, in the hope that, at your earliest convenience, you will notice it again.

In speaking of the choice given to students by the Apothecaries' Society of attending botanical lectures *either* during the *first* or *second* summer of their studies, you recommend them to do so

in the *first*, "because in the *second summer* they will be occupied by *midwifery, with the diseases of women and children*, forensic medicine, and the medical practice of an hospital." Again, you say "the practice of midwifery, which the student will attend during his *second summer* and *third winter* session, is in one respect better taught," &c. &c. The manner in which these remarks are put will necessarily lead your readers to believe that the Apothecaries' Society require the obstetric class to be attended during the periods which you mention. Such, however, is not the case, as you will find by referring to their regulations published last month. It is there stated that two courses of midwifery must be attended in separate sessions, subsequently to the termination of the first summer session; and consequently it is left to the student's discretion whether he shall attend this branch during the two last winters, or during either of them and the intervening summer.

Now, sir, with this choice before him, it appears to me that it will be much for the student's advantage to attend the required courses of theoretical instruction during the *two last winters*, and devote the intervening summer, as far as midwifery is concerned, to gaining practical information, by taking charge of cases of labour. The following are among my reasons for this opinion:—

Every body will acknowledge that a student should not be entrusted with the care of obstetric cases until he has attended at least the whole of one course of instruction. By deferring his attendance, then, till the second summer, he has only the last winter session left in which to apply himself to this indispensable part of his duties. In this session more is required of him than in any of the former, and his time is consequently more taken up. Besides, he must devote as many hours as he can spare from the class-rooms and hospital wards, to preparing himself for the examinations he will have to undergo in the ensuing spring. It is reasonable, therefore, to suppose that he will neglect the opportunities offered him of making himself practically acquainted with the obstetric science, or will only attend a sufficient number of cases to entitle him to a certificate. From fifteen years' experience in teaching, I know how difficult it is to persuade

pupils to take charge of midwifery patients during the last winter of their pupilage; and how frequently—nay, almost universally, the time occupied in reading up for their approaching examinations is brought forward as an excuse for this neglect.

Students will also find it both more pleasant, as well as more convenient, to devote as much time as they can spare to practical midwifery, in the summer, for then the nights are short, the weather generally fair, and the annoyance of attending cases by no means so great. It is certainly desirable that they should give up some portion of the last winter to this duty; but it is even more desirable that they should qualify themselves for it before the commencement of the second summer.

Another objection to their attending midwifery lectures in the second summer is, that their time is as much, if not more, occupied during that session than in the second winter, although such does not appear the case at first sight. They will have forensic medicine to attend, and many of them botany, unless they have attended this class at a provincial school; because, in fact, as the Apothecaries' Society do not positively require any certificates of attendance for the first summer, few will remain here during it. They will have to attend the medical practice of an hospital, most of them will be attending the surgical practice at the same time, and they will be twice a week drawn away to Chelsea, which breaks up the whole day. Now as the session only comprises three months, (half the term of the winter session,) and as the course of midwifery lectures is required to consist of sixty, it is evident (when we consider the many interruptions that must occur in this particular department) that a lecture must be given at least five times a week; and even this arrangement would only leave six extra days for casualties. The probability is, that however well the teacher may have laid his plans, on one day in the week he will find himself addressing empty benches, his pupils being at the Botanical Gardens. It may, indeed, be answered, that the Gardens shut at noon, and there is plenty of time for the students to return; not so if the lecturer has chosen an early hour in the morning; and in truth I have found that, on these days, little is at-

tended to by the students after their Chelsea jaunt.

My recommendation to a young man entering the profession would be, to attend as much in the dissecting-room and class-rooms as he possibly can during the winter, and as much to the practical department of his profession during the summer; for I am certain that one feels much less inclination to be confined to the close air of a lecture theatre in the fine sunny days of summer, than in the close disagreeable winter weather; and that with the best resolutions the most attentive person is often inclined, on such days, to play the truant. It was so with me when I was a student; it has been so with my summer classes always; the feeling is inseparable from the buoyant disposition of youth; and if we preach till doomsday we shall not correct it.

I am sir,

Your very obedient servant,

FRANCIS H. RAMSBOTHAM.

14, New Broad Street,
October 17th, 1838.

EXOSTOSIS OF SCAPULA.*

To the Editor of the Medical Gazette.

SIR,

I BEG to transmit to you the following case of exostosis from the anterior surface of the scapula, which, from its extremely rare occurrence, you may perhaps think worth placing upon record in your journal. So far as I am aware the case is unique. Several of our most experienced hospital surgeons have told me that they have never had occasion to operate for a similar affection so seated.

John Reid, æt. 13, residing at No. 5, Warren Street, Tottenham Court Road, was brought to me the latter end of June, 1838, on account of a very considerable projection of the inferior angle of the right scapula, attended with pain after exertion, loss of power, and diminished freedom of motion in the right upper extremity. I found the inferior angle of the scapula thrown out from the ribs nearly two inches above its level, which was caused by a tumor, the size of a large walnut, growing from that surface of the scapula next the ribs, near its inferior angle, and pro-

jecting beyond the inferior costa, and nearly as far as the base of this bone; so that two sides of the tumor could be felt, but the rest being covered by the scapula, one could only judge that it was an exostosis from the hardness of the projecting portion, and from its unyielding attachment with the scapula. The tumor had latterly increased in size, and from its position between the scapula and ribs, so compressed and rubbed upon the soft parts lying on the latter, that the patient began to be incapable of following his occupation, in which he was frequently obliged to lift and carry parcels of considerable weight.

On Thursday, July 5th, 1838, I operated in the following manner. After reflecting a triangular flap of integument covering the infra-spinatus, I dissected the border of the latissimus dorsi from off the inferior angle of the scapula, so as to get the bone from under this muscle. The humerus being then raised to the patient's head so as to throw out from the thorax the inferior costa of the scapula, I detached from it the *teres major*. I then divided close to the base of the scapula the greater part of the insertion of the *rhomboideus major*, and with it the corresponding portion of the *serratus magnus*. I now passed my finger beneath the scapula, to feel the extent of the tumor, which had made its way between the fibres of the *subscapularis*, and having cut across the *infra-spinatus* down to the *dorsum* of the scapula, I divided with a pair of Liston's small-bone forceps the inferior costa of the scapula, and with it part of the *subscapularis*, about midway between the inferior angle and the insertion of the long head of the *triceps*. I then with the forceps cut through the base of the scapula towards the first division of the bone, and by bending the tumor backwards, broke the intervening part of the *dorsum*, and the tumor being held only by a small portion of the *subscapularis*, was immediately detached by a stroke of the scalpel. There was not much hæmorrhage; I tied but three arteries, and fastened with one stitch the cut fibres of the *teres major* to those of the *infra-spinatus*, and in like manner to the same muscle I fastened the detached portions of the *rhomboideus major* and *serratus magnus*. I secured the cut edges of the integuments in contact by five stitches, and a few strips of adhesive plaster, without any other

dressing. On the following day (Friday) the patient's pulse had risen to 112, but otherwise there was very little constitutional disturbance. He had taken an opiate immediately after the operation, and I now ordered him some calomel and jalap, and as he complained of heat in the wound, I directed that linen dipped in cold water should be constantly applied to it, at least until he should begin to feel chilled.

On the next day (Saturday) I found the patient almost free from pain, and without the least constitutional disturbance, his pulse having fallen to 84. He continued doing well; there seemed to be no suppuration except in the course of the ligatures; and eight days after the operation he walked from his home to my residence, a distance of about a quarter of a mile, at which time the wound was firmly healed, save where it had gaped between the stitches, which parts had only to cicatrize. On the 30th of July (three weeks and a half after the operation) I saw the patient: he was quite well, the wound being firmly cicatrized in its whole line, but his right upper extremity much weak-

ened. Between nine and ten weeks after the operation I again saw him. He was free from pain, and his right arm had become as strong as the other, and possessed the same extent and freedom of motion; so far, that for two weeks past he had resumed his former occupation.

I have the honour to be, sir,
Your obedient servant,
W. M. BEAUMONT.

47, Berners Street, Oct. 17, 1838.

DELIRIUM TREMENS.

To the Editor of the Medical Gazette.

SIR,

SHOULD you consider the following case worthy of insertion in your valuable journal, you will greatly oblige,

Your obedient servant,
WILLIAM GARLIKE.

42, Theobald's Road.

Delirium Tremens treated with Tartar Emetic and Opium.

I was desired at six o'clock on the evening of the 25th of September, 1838, to see Mrs. —, æt. 38, who had early on the same morning lost her father, upon whom she had been in continual attendance for the last three weeks, and in consequence had received but little rest. The following symptoms presented themselves. Walking about the room in great nervous excitement, and requiring strong force to prevent her leaving it, incoherent talking, convulsive sobbing, fixed stare of the eyes, conjunctiva injected, pupils natural, pulse small and weak, skin hot, and great thirst, coupled with complete wakefulness.

R Tr. Opii ʒj.; Tr. Lavand. Comp ʒj.; Spt. Ammon. Aromat. ʒj.; Mist. Camphoræ ʒv. M. ft. Haust. statim sumend. I ordered her to be put to bed.

8 o'clock same evening.—Has been to bed.

R Tr. Opii ʒiv. Spt. Ammon. Aromat. ʒij.; Aquæ ʒv. M. ft. Mistur. Cap. Coch. Magn.; omni hora. Cold applications to the head.

12 o'clock.—No improvement; distressing sickness; every thing ejected as soon as taken; mistakes every one

Form and Dimensions of a Section of the Exostosis.

a, the dorsal aspect of the inferior angle of the scapula.

b, a continuation of the cancellous structure of the scapula into the exostosis.

c, a firmer osseous structure without cancelli.

d, a thick layer of cartilage, which covered the whole of the exostosis, and which was as hard and compact as articular cartilage.

for her father, and fancies him still alive. Previous to this last visit I consulted with my friend Mr. Larkins, who advised the following to be given.

R Tr. Opii, ʒij.; Antim. Pot. Tart. gr. j.;
Mistur. Camphoræ, ʒvss.; M. ft. Mist.
Cap. Coch. Magnum, omni hora.
Continue cold applications to the head.

26th, 9 A.M.—Violent headache, sickness, vomiting, and other symptoms, continue unabated. One dose of the last medicine had only been given, from the attendants fearing it had kept up the sickness. I ordered it to be given regularly every hour.

12 A.M.—Has taken the medicine regularly; sickness very much abated; remained quiet for about ten minutes.

27th, 4 P.M.—Slept soundly from three o'clock yesterday afternoon till to-day, when she was awoke by noises in the adjoining apartment, but had not again slept. The medicine had been given every hour from the time she awoke; had taken some porter; talks much more rationally, yet thinks her father alive; *no sickness*, pulse soft and natural, bowels confined.

Continue cold applications to the head, and mixture. Allowed beef tea.

28th.—Slept all the night; quite composed; talks rationally on all subjects save her father, under which delusion she still continues. Bowels being confined, ordered some aperient medicine; mixture continued, but in smaller doses.

29th.—Rather restless, with headache; has not mentioned her father. Cold to the head, and the following draught every six hours:—

R Morphiæ Hydrochlor. gr. $\frac{1}{4}$; Tr. Lavand. Co. ʒj.; Aquæ ʒxj. M. ft. haust.

30th.—Slept all night, and continued quiet till one o'clock, when her father's body was removed, the noise of which disturbed her. Ordered no medicine. Wine allowed.

8 P.M., same day.—About an hour previous to this visit she was lying rather more composed, when she suddenly started up, with the exclamation, "I remember all!" from which time she has continued perfectly conscious of her father's death.

Oct. 1st.—Much better; great prostration of strength; tongue furred and moist; pulse hardly perceptible.

R Quinæ Disulph. gr. j.; Sr. Aurantii, ʒss.; Aquæ ʒj. M. ft. haust. sumend. ter die.

2nd.—Much better. Continue medicine.

4th.—Convalescent.

OBSERVATIONS.—In presenting this case to the notice of the profession, my object has been to point out a remedy, or rather a conjunction of remedies, which are not generally used in this affection. I of course allude to the tartar emetic and opium, a plan for which we are solely, I believe, indebted to that experienced physician, Dr. Graves, of Dublin, who has strongly inculcated this practice. It may be objected by many, that had the opium been continued alone it might have produced, or perhaps did produce, the beneficial effects I am inclined to attribute to both; but it is fair to argue, that if the opium had (from the necessarily large quantities given) had the desired effect, it must have shown itself earlier; for it must be borne in mind, that no less than five drachms of laudanum had been given to a person totally unaccustomed to stimuli, in the short space of six hours, while no improvement actually took place till the tartar emetic and opium had been regularly administered. It is also worthy of remark, that when the patient was getting under the influence of the above remedy, the sickness was much relieved.

VACCINATION.

To the Editor of the Medical Gazette.

SIR,

THE interest excited by the papers which have lately appeared in the MEDICAL GAZETTE, on the subject of Vaccination, induces me to think that you may not deem the following communication unworthy of insertion:—

Within the last three years I have twice tried reputed vaccine matter taken directly from the cow. The first was sent by a surgeon at Cricklade, to a physician practising in this town. The second was taken by a surgeon here, with his own hand. They both failed, and the failure must be attributed to some imperfection of the lymph, since, in both instances, several other practitioners used matter from the same source, unsuccessfully.

About the middle of last month I received from a retired surgeon residing here, three points (which were sent him by a most respectable practitioner at Berkeley) charged with lymph two removes from the cow, and taken from a very healthy child. Lest I should expend my whole stock on an unpropitious subject, I selected three healthy children, and appropriated a point to each. No. 1 did not take at all. I saw No. 2 at dusk on the evening of the eighth day, when there was but one small imperfect vesicle, which I pronounced to be unsatisfactory, and said I would re-vaccinate the child in a few days. I went on the fourteenth day, and found the pustule advanced to the stage which it usually attains on the tenth, and which would at that time be deemed satisfactory. The mother was satisfied with it, and would not permit re-vaccination. I vaccinated No. 3, Mary Jones, æt. 10 weeks, on September 19th, who had three small vesicles on the eighth day, not more mature than is ordinarily seen on the seventh, and containing very little lymph. From one vesicle I vaccinated Fanny Molesworth; and being promised by the mother to come on the morrow (who, however, failed to do so), I took no lymph on glasses or points. Fanny Molesworth, æt. 10 weeks, was vaccinated Sept. 26; had two fine vesicles on Oct. 4, from one of which I vaccinated — Scott, æt. 8 months, and Josiah Lewis, æt. 7 weeks. The latter did not take; the former had three fine vesicles, from one of which I was permitted to charge two glasses. From one glass I vaccinated, Oct. 15, Theophilus Cook, æt. 3 months, and found three fine vesicles this morning, two of which furnished sufficient matter for five glasses. From the other, — Browne, æt. 14 weeks, was vaccinated Oct. 13; two fine vesicles were the result, from one of which I charged three glasses on the 21st, and used one this morning, so that I can now afford to supply my neighbours who may wish to try this recent stock. On October 15th I was sent for to see Fanny Molesworth, on account of the bad appearance of the poeks. On the 16th they got worse, presenting “deep circular cavities” (see Mr. Estlin’s second letter), and I was politely requested (*if it would at all relieve my mind*) to call in a physician, which I chose to decline. They are now well.

The vesicles have in general been more retarded than usual, and hardly so fine as those which I ordinarily observed during the last spring; and I have heard several surrounding practitioners assert that the matter kindly furnished by Dr. Gregory to the Provincial Medical and Surgical Association, produced no finer vesicles than those which they have long been in the habit of seeing. I wish that some one with more extensive opportunities than I have would note the varieties as to time, course, size, and perfection, of the vesicles, induced by the quantity of matter introduced, the mode of introduction, and the state of the weather.

I am, sir,
Your obedient servant,
HENRY COLES.

Cheltenham, Oct. 23rd, 1838.

MEDICAL GAZETTE.

Saturday, October 27, 1838.

“Licet omnibus, licet etiam nihil, dignitatem
Artis Medicæ tueri; potestas modo veniendi in
publicum sit, dicendi periculum non recuso.”

CICERO.

THE MANAGEMENT OF MAD- HOUSES.

In our last article on this subject (Oct. 6) we ventured to hope that matters were not quite so ill managed as Dr. Crowther represents them to be even in asylums enjoying a good repute; yet if we believe the evidence lately adduced at a coroner’s inquest in Hampshire*, it would seem that Dr. Crowther’s censure errs on the side of mildness, and that mad-houses have returned to the state depicted in the Parliamentary Reports of 1815. The inquest, which lasted five days, was held upon the body of Mary Ann Stroug, a pauper lunatic confined in Mrs. Middleton’s asylum at Grove Place, about four miles from Southampton. The deceased had been removed from the asylum, and died six days afterwards, in consequence, as was sup-

* Times of October 15th. From the Hampshire Independent.

posed, of the treatment which she had received there.

Mary Ann Sturdy, the first witness, deposed that on Friday, the 28th of September, the deceased was brought home in a violent state, with bruises on the face, neck, and back—"from the poll of her neck to nearly the bottom of her back was quite black." On the Saturday evening she was secured with a rope, and on Sunday with a strait waistcoat, but had no medical attendance while the witness was with her.

Frances Sturdy deposed to having seen the deceased on the 29th of September, when she was sent for to attend her; she remained with the deceased till her death. Mrs. Strong said to the witness, when she washed her on the 30th, "I hope you are not going to wash me with a birch-broom, and throw a pail of water over me."

Mr. E. Shakell, brother of the deceased, stated that he had applied to the Board of Guardians on the 20th of September, to have his sister removed from Grove Place, where she had been about three months. He did this on account of information which he had received as to her treatment there. Some preliminaries had to be settled, and he saw the Board of Guardians again on the 27th, when the final arrangements were made.

Mrs. Willis, who had been confined in the asylum at the same time as Mrs. Strong, deposed to the treatment to which the latter was subjected. She had seen her standing in the middle of the yard entirely naked, and washed by a nurse named Caroline Sellens; the water being thrown upon her from a bucket. "She was driven down stairs from her bed-room into the yard, quite naked, where cold water was thrown over her, and afterwards she was driven into the straw-house in that state; it was Caroline Sellens who drove her and struck her several times: she repeated the blows all the way down stairs, and

again repeated them in the yard; she was quite naked all the time, and the blows were chiefly upon her back; this particular beating occurred about two months before I left the asylum, as nearly as I can recollect; I have seen Mrs. Strong beaten after the time I have been describing; it was continued almost daily until the time that I left."

Some discussion took place between two of the attorneys attending the inquest, on the admissibility of this witness's evidence, as she was insane in presumption of law at the period when these events happened. To this it was answered, that in lucid intervals lunatics were held to be legally competent and responsible agents. The witness, in fact, was actually entrusted with the keys of the outer gate for some months, and seems, therefore, to have had more than lucid intervals. Among her ordinary duties she had to dress a young woman named Emma Francis, who was very violent. The witness, who had left the room, was now recalled, her evidence being admitted under protest, and she immediately recollected the last words she had uttered, which, as Hamlet says, "madness would gambol from." Several of the jury, indeed, expressed their opinion that she was as competent to give evidence as any person in the room; but it remains to be seen, if the case should be carried into another court, whether it can be legally proved that she was in a lucid interval when entrusted with the keys. This doubt applies to another important witness, Mrs. Fanny Smith, who likewise saw the treatment inflicted on the deceased; these being, indeed, the only witnesses who did see it. Mrs. Strong having been visited by Mrs. Shakell, her sister-in-law, had revealed some of the secrets of her prison-house (as appears from the evidence of the latter), on which, says Mrs. F. Smith, "Sellens told Mrs. Strong that she should be stripped stark

naked, and sent to bed without supper, for telling 'they lies to Mrs. Shakell:' that evening witness saw her stripped naked, and sent up without supper. Witness saw that, and heard the screeches after she was up stairs."

This witness frequently saw the deceased beaten with a stick, but did not dare to mention it; "if she had, she should have been served so herself."

The next witness was Dr. Henry Clark, surgeon to the guardians of the poor, who confessed that neither a lunatic, nor a person in a lucid interval, ought to have charge of the keys of the outer gates of a lunatic asylum; that a patient in delicate health ought not to be exposed, undressed, in the open air for a quarter of an hour, with a bucket of water thrown over her, &c.; in short, he made a number of admissions very unfavourable to Grove Place, if the previous evidence be true.

Mr. C. Fowler, a surgeon, gave an account of the post-mortem appearances. The back, thighs, and legs, had numerous discolorations caused by external violence; "the darker coloured appearances on the back he believed to arise from the gravitation of the blood after death, and consequent upon death; did not attribute the whole of the discoloration of that part of the body to the same cause." There was some opacity in the superior longitudinal sinus, and more fluid than usual in the lateral ventricle. The right ventricle of the heart was dilated, and its walls very thin; there was a strong adhesion between the pleura pulmonalis and costalis. The intestines were greatly distended, particularly the larger ones. Mr. Fowler was of opinion that the death of Mrs. Strong depended on these appearances, though in another person they might have been compatible with life. This opinion, though at first sight paradoxical, is by no means indefensible; thus, for example, an organic dis-

ease of the heart may extinguish life in one patient, while another lives on though oppressed by a higher degree of the same malady.

Soon afterwards we have the evidence of a witness said to be *recalled*, but not mentioned before, by name Frances Ryder. This is apparently the person before called Frances Sturdy. She mentioned her having administered jalap and salts to the deceased without effect, after her removal from Grove Place, and said that she did not think there was any occasion to call in medical assistance.

Mr. Thomas Simpson, the surgeon of Grove Place Asylum, deposed to Mary Ann Strong having been admitted on the 11th of June. He examined her person within an hour or two of her admission, and found marks of violence on her back, extending from the lower part to nearly as high as between the shoulders. He also bore witness to the violence with which the deceased struggled out of her strait waistcoat, threw herself on the floor, and shifted one of the straps of the leather sleeve which she afterwards wore, so as to injure her neck. He never saw any violence used towards Mrs. Strong, either by beating her with a stick, or otherwise; and neither she, nor any one for her, ever complained to him of ill usage. Hence his evidence went to show, not only that Mrs. Strong came into the asylum covered with bruises, but that from her violence while residing there, these bruises were renewed. The certificate for her admission was signed on the 5th of May, but she was not admitted till the 11th of June. This seems strange. Concerning the two principal witnesses, he was of opinion that Mrs. Willis was insane during her residence in the asylum, and had not perfectly recovered when she left it on the 4th or 5th of August; and that Mrs. Smith was

insane, but was rather better on the 28th of September, when she left the asylum, than when she was there.

The coroner, previously to delivering his charge to the jury, read them a letter which he had just received from Mrs. Middleton, addressed to himself and the jury, stating that she had discharged Mrs. Rose and Caroline Sellens from the asylum; though from the inquiries she had made, she believed them to be innocent of the charges brought against them. The verdict of the jury was, "The jury are of opinion, that the death of the said Mary Ann Strong was occasioned by natural causes, accelerated by the ill treatment she experienced from the two nurses, Mrs. Rose and Caroline Sellens, during her confinement in Grove Place Lunatic Asylum."

We can scarcely venture to offer a positive opinion on this perplexing case, and would hardly wish to do so, as it may probably be again mooted in a criminal court. Were the chief witnesses, Willis and Smith, really, or nominally, insane during the latter part of their residence at Grove Place? If the former, and we admit their evidence, the nurses were injured persons; if the latter, and we reject it, guilt will escape its due punishment. The truth is, that the difficulty of admitting the evidence of the insane against their keepers, is like that of admitting the evidence of blacks against whites in slave colonies. If the evidence is freely admitted, no white is safe; if entirely rejected, no black. And just as a man, in spite of his ebony skin, may be an honest witness, so a person confined in an asylum may, in spite of some eccentricities, be a calm and competent observer of all that is going on around him. As for the surgeon of such an establishment, his negative evidence, his not seeing, cannot go for much—the masters of a public school do not see the tyranny practised

by the big boys upon the fags. Even if the task of superintendence were more easy, it would be in vain, we fear, to expect much from our modern guardians of the poor; we should rather be tempted to ask,

Quis custodiet Ipsos
Custodes?

One of the most remarkable points in the whole evidence is, the constant absence of Mrs. Middleton, the proprietress of the asylum. Mrs. Willis never saw her at all.

What will Dr. Crowther say to all this, and what remedy will he propose? The same, we suspect, which would occur to every man of common sense and honesty. Let a public asylum be built in each county that does not possess one, so that indigent lunatics may be saved from the horrors of mismanaged private establishments.

We return, after this digression, to the consideration of Dr. Crowther's strictures and proposals. There is no office in the profession so difficult to fill, he says, as that of physician to a lunatic asylum, and no wonder, if it demands half the qualifications which he sets forth. There are three classes of physicians, he tells us. The first, who are divided into several sub-genera, are your routine physicians. The second kind consist of scientific physicians, without practical tact, who talk learnedly and elegantly on every subject connected with medicine, but are nonplussed if they have to treat a complicated case. The third kind consist of physicians who combine every qualification, and who are admirably adapted for a lunatic asylum; or, we should imagine, for anything else. There is a pleasant story of a lady, who, being in want of a governess, wrote to her brother, describing the varied perfections she required, and requesting him to look out for her. He replied that he had long been in search of such

a person, but if he ever should be so fortunate as to find one, he intended to make her, not his sister's governess, but his own wife. Now, if such a physician is to be found as Dr. Crowther requires, (and at a moderate salary too), for a lunatic asylum, we should recommend him straightway to repair to London, where we would guarantee him a practice of at least ten thousand a year. Enough—said the Prince to Imlac—you have convinced me that no man can ever be a poet; enough, Dr. Crowther, you have convinced us that no man can ever be physician to a lunatic asylum. Nevertheless, the attempt to obtain perfection is a laudable one, and may assist in procuring the services of an officer, who, though many degrees below the Crowtherian standard, might still be a man of great merit.

LONDON UNIVERSITY.

WE subjoin, for the edification of the public, the regulations which it is proposed to adopt at the London University, in reference to granting degrees in medicine. None but mere theorists would have indited such a document; and as we understand that they invite "remarks," we shall take the liberty of making a few next week.

REPORT OF THE COMMITTEE OF THE FACULTY OF MEDICINE

ON THE
Subject of granting Degrees in Medicine.

CANDIDATES for Degrees in Medicine shall be required to have taken a Degree in Arts in this University, or in a University the Degrees granted by which are recognised by the Senate of this University; or, they shall be required to have passed the 'Examination in Arts' for Medical Students, conducted by the Examiners in Arts of this University.

EXAMINATION IN ARTS.

The examination in Arts shall take place twice a year, in the months of May and October.

Every candidate, at least fourteen days before being admitted to this examination, shall transmit to the registrar a certificate showing that he has completed his seventeenth year.

A fee of 5*l.* shall be paid before exami-

nation. If the candidate fail to pass the examination, the fee shall be returned to him.

The examination shall be conducted by means of printed papers; but the examiners shall not be precluded from putting *vivâ voce* questions on the written answers, when these appear to require explanation.

Candidates for this examination shall be examined in the following subjects:—

The Greek and Latin languages.—One Greek and one Latin subject, of a specified extent, to be selected one year previously by the Committee of the Faculty of Arts from the works of the under-mentioned authors:—*Homer*, one book; *Xenophon*, one book; *Virgil*, one book of the *Georgics*, or the sixth book of the *Æneid*; *Horace*, one book of the *Odes*; *Sallust*, *The Conspiracy of Cataline*, or the *War with Jugurtha*; *Cæsar*, *The Civil War*, or the fifth and sixth books of the *Gallie War*; *Livy*, one book; *Cicero*, the treatises *De Senectute* and *De Amicitia*, or two of the shorter or one of the longer orations.

The grammatical structure of the English language.

The French language or the German language.

History and geography.—History of Greece to the death of Alexander; History of Rome to the death of Augustus; History of England to the end of the seventeenth century; the outlines of ancient and modern geography.

The papers in classics shall consist of passages to be translated, accompanied by questions in grammar, history, and geography.

Proficiency in English composition will be judged of by the style of the answers generally.

Arithmetic and Algebra.—The ordinary rules of arithmetic; vulgar and decimal fractions; extraction of the square root; addition, subtraction, multiplication, and division of algebraical quantities; proportion; arithmetical and geometrical progression; simple and compound interest; discount, and annuities for terms of years; simple and quadratic equations; use of logarithms.

Geometry.—The first book of Euclid; mensuration of surfaces and solids of the simpler forms.

Mechanics.—Composition and resolution of forces; the mechanical powers; centre of gravity; general laws of motion; motion of falling bodies in free space and down inclined planes.

Hydrostatics, hydraulics, and pneumatics.—The pressure of fluids is equally diffused, and varies with the depth; the surface of a fluid at rest is horizontal; specific gravity; a floating body displaces exactly its weight of the fluid, and is supported as if by a force equal to that weight pressing

upwards where the centre of gravity of the displaced fluid if restored would be; weight and pressure of the atmosphere; the barometer; theory of winds; the siphon; common pump and forcing pump; the air pump; the diving-bell; the steam-engine.

Acoustics.—Impulses propagated through the air, or other medium, to the ear, produce the sensation of sound; similar impulses following quickly at equal intervals, are heard as a continuous sound, of which the pitch depends on the number of impulses in a given time; such impulses reflected from surfaces constitute echos.

Heat.—The general phenomena of radiation and conduction, of the expansion of bodies, and of the changes from one to another of the solid, liquid, and æriform states; the thermometer; temperature of the atmosphere; hygrometrical condition of the atmosphere; theory of dew.

Electricity and magnetism.—The general facts.

Optics.—The laws of reflection and refraction; lenses; the camera obscura; the telescope; the microscope; the eye considered as an optical instrument.

Astronomy.—The apparent motion of the heavens round the earth; the apparent motion of the sun through the fixed stars; the phenomena of eclipses; general arrangement of the solar system.

Elements of logic.

Elements of moral philosophy.

No candidate shall be approved by the examiners unless he show a competent knowledge in all the subjects of examination.

Candidates who have matriculated in Arts will be exempted from examination in Greek and Latin, in history, geography, and mathematics, and shall pay a fee of only 3*l*.

Degree of Bachelor of Medicine.

Candidates for this degree shall be required to produce certificates, showing that, subsequently to having taken the degree of Bachelor of Arts, or to having passed the examination in arts for medical students, they have been engaged during four years in the study of medicine, and have attended courses of instruction on the following subjects, and of the extent here specified, at one or more medical institutions or schools recognized by this University:—

Minimum number of lectures.—Botany, 40; materia medica and pharmacy, 80; chemistry, 80; descriptive anatomy, 100; comparative anatomy, 40; physiology and general anatomy, 100; general pathology and pathological anatomy, 60; general therapeutics, 40; principles and practice of medicine, 80; principles and practice of surgery, 80; midwifery and diseases of women and infants, 50; medical jurisprudence, 40; hygiene, 40; practical chemistry, 30 lessons; practical anatomy, two winter sessions; clinical medicine and surgery, in an hospital, during the last three years of the medical curriculum; practical medicine and surgery, in an institution in which the treatment of patients is entrusted to the senior pupils under the superintendence of the medical officers, during six months.

Previously to the year 1841, attendance on separate courses on the following subjects will not be insisted on:—Physiology and general anatomy; general pathology and pathological anatomy; general therapeutics. The academical year shall consist of a winter session and a summer session; the former to continue not less than six months, the latter not less than three months.

ORDER OF STUDY.

The following is recommended as the order of study:

<i>Winter Session.</i>	FIRST YEAR.	<i>Summer Session.</i>
Descriptive anatomy.		Comparative anatomy.
Chemistry.		Practical chemistry.
Materia medica and pharmacy.		Botany.
	SECOND YEAR.	
Physiology and general anatomy.		General pathology and pathological anatomy.
Practical anatomy.		General therapeutics.
Principles and practice of surgery.		Clinical instruction.
	THIRD YEAR.	
Principles and practice of medicine.		Midwifery and diseases of women and infants.
Practical anatomy.		Clinical instruction.
	FOURTH YEAR.	
Hygiene.		Medical jurisprudence.
		Clinical instruction.
	Practical medicine and surgery.	

Previous Examination.

The previous examination shall take place twice a year, in the months of May and October.

The candidate, before being admitted to this examination, shall be required to produce certificates showing that he has been engaged during two years in the study of medicine subsequently to having passed the examination in arts.

The fee for this examination shall be 2*l*. If the candidate fail to pass the examination, the fee shall be returned to him.

The examination shall be conducted partly by means of printed papers, and partly by *visà voce* interrogation. The student shall be called upon to point out and describe the different objects under examination.

Candidates shall be examined in the following subjects:—Descriptive anatomy, chemistry, botany, materia medica and pharmacy.

Examination for honours.—Candidates who have passed the previous examination, and who have produced certificates that they have not completed their 21st year, may be examined for honours in the following subjects:—Anatomy, materia medica and botany, chemistry and pharmacy. The examination shall be conducted by means of printed papers.

In each of these three subjects, a gold medal of the value of 5*l*. shall be awarded to the candidate who shall distinguish himself the most, if in the opinion of the examiners he possess sufficient merit: and should one candidate obtain two of the medals, he shall further receive 30*l*. per annum for the next two years from the University chest.

Examination for the Degree of Bachelor of Medicine.

The examination for the degree of Bachelor of Medicine shall take place twice a year, in the months of May and October.

No candidate will be admitted to this examination within two years after having passed the previous examination.

The candidate shall be required to produce a certificate of moral character from a teacher of each school or institution at which he has studied, as far as the teacher's opportunities of knowledge extend.

The required certificates shall be transmitted to the registrar at least fourteen days before the examination begins.

The fee for the degree of Bachelor of Medicine shall be 15*l*. If the candidate fail to pass the examination, the fee shall be returned to him.

The examination shall be conducted partly by means of printed papers, and partly by *visà voce* interrogation.

In anatomy, the candidate shall be re-

quired to dissect a portion of the human body, and to demonstrate from preparations; and in chemistry, to show his power in testing, and generally in chemical manipulation.

[When the necessary arrangements can be effected, the candidate's practical knowledge in medicine and surgery will be tested at the bed-side.]

Candidates shall be examined in the following subjects:—

First day.—Descriptive anatomy, general anatomy and physiology, surgery.

Second day.—Chemistry, medical jurisprudence, midwifery and the diseases of women and infants.

Third day.—General pathology and therapeutics, hygiene, practical medicine.

Examination for Honours.

Bachelors of medicine who have produced a certificate that they have not completed their 25th year, may be examined for honours in one or more of the following subjects:—Anatomy and physiology, surgery, medicine.

The examination shall be conducted by means of printed papers.

In anatomy and surgery, the candidate shall also be required to dissect and demonstrate.

In each of these three subjects, a gold medal of the value of 10*l*. shall be awarded to the candidate who shall distinguish himself the most, if in the opinion of the examiners he possess sufficient merit; and should one candidate obtain two of the medals, he shall further receive 50*l*. per annum for the next three years from the University chest, with the style of University Medical Scholar.

Degree of Doctor of Medicine.

The examination for the degree of doctor of medicine shall take place once a year, in October.

Candidates for this degree shall be required to produce certificates that, subsequently to having taken the degree of bachelor of medicine, they have attended to practical medicine for the space of two years in an institution recognised by this University, or have been engaged during five years in the practice of their profession. One year of attendance in an institution for practical instruction will be considered equivalent to two years of practice.

Candidates shall also be required to produce a certificate of moral character from two persons of respectability, fourteen days at least before the examination.

The fee for this degree shall be 25*l*. If the candidate fail to pass the examination, the fee shall be returned to him.

Candidates shall be examined in the following subjects:—

First day.—Physiology, medical jurisprudence, practical medicine.

Second day.—General pathology and therapeutics, hygiene and medical statistics, mental diseases.

Thesis.—The candidate shall be required to write and defend a thesis on some branch of medical science, or of one of the collateral sciences. The thesis may be written in English or in Latin, and must be delivered to the registrar at least fourteen days before the examination.

Certificates of Proficiency.

Candidates who desire to obtain a certificate of proficiency in surgery or in midwifery shall, in lieu of the second part of the examination, undergo an examination in the subject in which they desire a certificate.

The desire to be examined for such certificate must be stated on the thesis when delivered to the registrar.

Doctors of Medicine of this University who, at a period subsequent to that of taking their degree, may be desirous of obtaining a certificate of proficiency in surgery or in midwifery, may be admitted to examination, on giving the necessary notice and paying a fee of 10*l*.

Medical Schools and Institutions.

Medical schools shall be required to possess ample means of illustrating their several courses of lectures; as, a museum of anatomy, of pathological anatomy, of materia medica and botany, a chemical laboratory, &c.

Lecturers shall examine their pupils after at least every fifth lecture.

Certificates shall be in the following form:—This is to certify that during the session of 18 attended my course of instruction on which consisted of lectures and examinations, and that he was present at examinations.

For *practical chemistry* the teacher shall certify that the pupil diligently operated during the course, which consisted of lessons; and for *practical anatomy* the teacher shall certify that the pupil dissected carefully during at least two winter sessions.

Certificates for more than two subjects will not be received from the same teacher.

Hospitals.

Each hospital shall accommodate at least one hundred patients.

A clinical lecture on medicine and a clinical lecture on surgery shall be given at least once a week.

The histories of the diseases shall be recorded in a journal, to be open to the inspection of the pupils.

The *post mortem* examinations shall be made in the presence of the pupils, and

the appearances recorded in the journal of cases.

Students already engaged in the Study of Medicine.

Students already engaged in their medical studies shall be required, during the time yet requisite for the completion of their education, to conform as far as possible to the course of study enjoined by this University.

Students of not more than two years' standing in October 1838, shall be required to pass the subjoined examination in arts and the *previous examination*.

Students of more than two years' standing in October 1838, shall be required to pass the subjoined examination in arts before being admitted to the examinations for the degree of Bachelor of Medicine.

They shall be required to produce a certificate that they have completed their twenty-first year; and also a certificate of moral character from a teacher in each school or institution at which they have studied, as far as the teacher's opportunities of knowledge extend.

The fee for the examination in arts shall be 5*l*.; for the examination in medicine, 20*l*. Should the candidate fail to pass either examination, the fee shall be returned to him.

Examination in Arts.

Latin.—Celsus, the first four books; Heberden's Commentaries.

Natural Philosophy.—As in the examination in arts.

Examination in Medicine.

The examination in medicine shall be the same as the examination for the degree of Bachelor of Medicine. Candidates who have not passed the *previous examination* shall also be examined in botany, materia medica, and pharmacy.

PRACTITIONERS DESIROUS OF OBTAINING DEGREES IN MEDICINE.

Degree of Bachelor of Medicine.

Legally qualified practitioners in medicine or surgery may be examined for the degree of Bachelor of Medicine.

The candidate shall be required to produce a certificate of moral character from two persons of respectability, fourteen days at least before the examination.

The fee for the examination in arts shall be 5*l*.; for the examination in medicine, 15*l*. If the candidate fail to pass either examination, the fee shall be returned to him.

* In order that the teacher may be enabled to certify attendance of the pupils at the examinations, it is recommended that at each examination a roll be called, and the absentees marked.

Examination in Arts.

The examination in arts shall be the same as that required of students already engaged in the study of medicine.

Examination in Medicine.

Candidates shall be examined in the following subjects:—

First day.—Anatomy, physiology, surgery.

Second day.—Chemistry, medical jurisprudence, midwifery and the diseases of women and infants.

Third day.—Materia medica and therapeutics, pathological anatomy, practical medicine.

Degree of Doctor of Medicine.

Legally qualified practitioners in medicine or surgery, of five years' standing, may, after having taken the degree of Bachelor of Medicine in this University, be examined for the degree of Doctor of Medicine at the next term for that examination.

The candidate shall be required to produce, at least fourteen days before the examination, a certificate of moral character from two persons of respectability.

The fee for this degree shall be 25*l*. If the candidate fail to pass the examination, the fee shall be returned to him.

Candidates shall be examined in the following subjects:—Pathology and therapeutics; hygiene, and medical statistics; mental diseases.

Thesis.—The candidate shall be required to write and defend a thesis on some branch of medical science, or of one of the collateral sciences. The thesis may be written in English or in Latin, and must be delivered to the Registrar at least fourteen days before the examination.

Examiners.

The number of medical examiners shall be fifteen; to form three sections according to the three parts of the examination for the degree of Bachelor of Medicine. The examiners for the previous examination, and for the degree of Doctor of Medicine, to be agreed upon each term.

The examiners shall be appointed at a meeting of the Senate, to be held in June or July. [The appointment for next year shall take place at a meeting of the Senate, to be held in February 1859.]

They shall continue in office for one year from the time of their appointment.

They shall have power to discontinue the examination of any candidate who may misconduct himself.

They shall each receive from the University chest.

UNIVERSITY COLLEGE MEDICAL SOCIETY.

Friday, October 19, 1838.

A PAPER was read by Mr. James Blake on—

The Action of various Substances on the Animal Economy when introduced into the Veins, more particularly as regards the Influence they exert in modifying the Circulation.

This paper was read before the medical section of the British Association, at Newcastle; but as no correct report of it has yet appeared, we have taken this opportunity of furnishing our readers with a short abstract of it.

Mr. Blake commenced by stating, that it was only in compliance with a wish, expressed by many members of the Society, that he had been induced to bring a communication before them, which had already been read before another society.

As the experiments brought forward were performed by the aid of the hæmadynamometer, a description of this instrument was given. The use of it is to enable us to ascertain the pressure of the blood on the parietes of the arteries; and as this pressure is immediately affected by any change in the action of the heart, or in the capillary circulation, we have a valuable instrument by which these changes can be instantly determined, and their amount observed*. The cause of the pressure of the blood on the parietes of the arteries, and the manner in which this might be modified, were then considered. It was shewn, that the pressure of the blood in the arterial system, as indicated by the hæmadynamometer, was only an expression of the force required to cause a certain quantity of blood to pass through the capillaries in a given time. Experiments were related shewing the effect of respiration on the action of the heart, and the changes produced in the circulation by the injection of blood and water into the veins.

After these preliminary experiments, the investigation of the action of those substances which exert a more decided effect on the animal economy was entered into. These were divided into three classes. The first were those which kill by acting directly on the contractility of the heart, and which, when injected into the veins, suddenly stop the contractions of that organ. The second class included those substances which, although causing death often more

* A description and drawing of this instrument will be found in Todd's *Cyclopædia of Anatomy and Physiology*, art. *Circulation*.

rapidly than the former, yet leave the heart apparently unaffected, the action of the poison being directly on the nervous system. The third class contained those which agreed in exerting a powerful influence in modifying the capillary circulation. The substances included in the first class, whose action had been experimentally investigated, were, the nitrate, arsenite, and carbonate of potass, carbonate of soda, ammonia, iodide of arsenic, oxalic acid, and galls. All these substances, when injected into the veins, stopped the pulsations of the heart in a few seconds. The injection of a solution, containing four grains of nitre, arrested the action of the heart in twenty-five seconds; respiratory movements and sensibility continuing for some seconds after the pulsations of the heart had entirely ceased. After death, the heart was found to have lost its irritability, the application of the galvanic stimulus not producing contractions two minutes after death. The left cavities of the heart contained scarlet blood. Experiments were related to shew the action of the other substances in this class, and a few general remarks were made on them. It was observed that the sudden manner in which the heart is stopped—the absence of irritability in that organ after death—the continuation of the respiratory movements after the cessation of the heart's action—the absence of any marked effects on the nervous system—and the time and manner in which death took place corresponding to that which is observed when excision of the heart is performed—all tended to justify the arrangement which had been made of these substances, as proving fatal by acting directly on the heart. The action of some of these substances, which appeared to be rapidly absorbed when taken into the stomach, as diuretics, was pointed out as affording an effectual means by which their accumulation in the blood to any amount was prevented. It is an interesting fact, that agreeing as all these substances do, in destroying the irritability of the heart, they should also possess the common property of producing marked chemical changes in the composition of the blood.

Experiments illustrating the action of the second class of substances, or those which produced death by acting directly on the nervous system, were then brought forward. They had been performed with strychnine, hydrocyanic acid, and conia. In every instance, no marked effect was exerted on the heart, which continued carrying on the circulation for some minutes after every external sign of life had ceased, as if

independent of the inanimate mass which surrounded it. It was ultimately stopped, in every case, by asphyxia. In entering on the consideration of the third class of substances, it was stated, that the grounds which had been taken for their classification, was not, as in the other classes, the manner in which they produced death; but the common property which they possessed, of acting on the capillary circulation. Solutions of euphorbium, tobacco, and digitalis, when injected into the veins, afforded striking examples of this. The injection of a solution of euphorbium into the jugular vein of a dog, was followed by the cessation of the action of the heart in twenty seconds; it remained suspended for thirty seconds, not the slightest movement taking place during that time; the heart again commenced pulsating, and in a few beats the pressure in the arterial system became increased to four times the amount it was before the commencement of the experiment. The pressure sustained by the parietes of the arteries was sometimes equal to a column of mercury of fifteen inches, or about seven pounds to the square inch. This great increase of pressure in the arterial system was considered to be owing to the passage of the blood through the capillaries being rendered more difficult, for the action of the heart did not appear to be increased. The cessation of the pulsations of the heart on the first injection of the substance, admitted of being explained on the supposition that the capillary circulation over its parietes is for a short time suspended by its immediate application. This explanation received confirmation from an experiment, in which a solution of digitalis was injected into the arteries. In neither of the two last classes of substances are to be found any which produce any striking change in the composition of the blood. Should they act by altering that fluid, the changes they effect are such as, in the present state of organic chemistry, we are unable to detect.

The action of morphia, cantharides, and nitric acid, when injected into the veins, was then considered. These substances would not admit of being placed in either of the above classes. The two former seemed to act directly on the heart, rendering its pulsations slower. Nitric acid appeared to produce death, by causing a mechanical obstruction to the passage of the blood through the lungs. A short detail of some experiments on the effect of the destruction of the spinal cord on the action of the heart, proved that this organ was not apparently affected by the sudden destruction of considerable portions of the cord.

HEALTH.

SOME popular American writers have lately laid hold of this subject, to the great advantage of the society in which they live. Dr. Combe's "Principles of Physiology" has gone through several editions, and I know that the demand of society for fresh air and soap and water has considerably increased in consequence. But much remains to be done. In private houses, baths are a rarity. In steam-boats the accommodations for washing are limited in the extreme; and in all but first-rate hotels, the philosophy of personal cleanliness is certainly not understood. The Creoles of Louisiana are the most satisfactory hosts and hostesses in this respect, except a few particularly thoughtful people elsewhere. In the house of a Creole, a guest finds a large pan or tub of fresh cold water, with soap and towels, placed in a corner of his room, morning and night. In such a climate as that of New Orleans, there is no safety nor comfort in anything short of a complete ablution, twice a day. On board steam-boats which have not separate state-rooms, there are no means of preserving sufficient cleanliness and health. How the ladies of the cabin can expect to enjoy any degree of vigour and cheerfulness during a voyage of four or five days, during which they wash merely their faces and hands, I cannot imagine. It is to be hoped that the majority will soon demand that there should be a range of washing closets in all steam-boats whose voyages are longer than twenty-four hours."—*Society in America*, by Harriet Martineau, vol. iii. pp. 151—2.

BOOKS RECEIVED FOR REVIEW.

The Principles of Surgery. By John Burns, M.D. F.R.S., Regius Professor of Surgery in the University of Glasgow. 2 vols. Longman and Co.

Chemistry of Organic Bodies—Vegetables. By Thomas Thomson, M.D. &c. &c. 1 large vol. Ballière.

Urinary Diseases and their Treatment. By Robert Willis, M.D., Licentiate of the College of Physicians, and Physician to the Royal Infirmary for Children. Sherwood and Piper.

An Examination of Phrenology, in two lectures, delivered to the Students of the Columbian College, district of Columbia, February, 1837. By Thoms Sewall, M.D. Professor of Anatomy and Physiology. James S. Hodson.

Practical and Surgical Anatomy. By W. J. Erasmns Wilson, Lecturer on Prac-

tical and Surgical Anatomy and Physiology. Longman and Co.

A Treatise on Neuralgia. By Richard Rowland, M.D. Member of the Royal College of Physicians of London, Physician to the City Dispensary. S. Highley.

LECTURES ON SURGERY,

DELIVERED AT ST. THOMAS'S
HOSPITAL,

BY THE LATE MR. CLINE;

With Notes.

[THESE lectures were written by Dr. Wilkinson when attending Mr. Cline's lectures, in the years 1787-88-89.

Extract of a letter from Dr. Wilkinson, dated Feb. 6, 1838:—"They (these lectures) are the results of six courses of lectures I attended at St. Thomas's, in 1787, 1788, and 1789; and I am in hopes I did not omit any interesting part of Mr. Cline's valuable observations. The one I had the pleasure of giving you is the repeatedly corrected copy."]

LECTURE V.

Operation for Inguinal Hernia—Congenital Hernia—Remarkable cases of Bubonocoele—Cyrural Hernia—Umbilical Hernia—Various other Hernia.

The operation for hernia.—This operation is attended with some degree of hazard at all times, therefore should not be performed without urgent necessity, which we can be directed to only by the symptoms of the patient. It is not the duration but the urgency of symptoms that must direct us, for sometimes it may be necessary in three or four hours after strangulation, at other times I have known the symptoms go on for eight or ten days before the operation was absolutely necessary. The symptoms vary very much according to the age of the patient. In old subjects, when there is a languid circulation, similar states of strangulation do not produce so immediately violent inflammation of the parts as where the circulation is carried on with greater

force, when inflammation is sooner in taking place, and hurrying on to the state of mortification.

When the symptoms have been very violent, succeeded by hiccup, which has generally been considered as a symptom of mortification, then we have no time to lose. I have known it very frequently arise before gangrene; however, it usually very soon follows. We should not always wait for the symptoms, for sometimes mortification hurries on so rapidly, that in so doing we may wait too long. The operation should be performed when the symptoms of inflammation are very violent, and the proper remedies have been applied with no effect, though the strangulation has not been present above three or four hours; for though the operation is very dangerous, there is more danger in delay. Also, when the operation is properly performed, and no unfavourable circumstances arise, I believe by far the greatest number would recover, for the only danger occurring from the operation (provided it has not been deferred too long), is from exposure of the cavity of the abdomen. Supposing all the necessary means have been used for the abatement of symptoms with little effect, we should then propose the operation to the patients; urging the necessity of submitting to it, and the great danger there is in delay should be strongly enforced.

To perform this operation the patient should be placed at a convenient height on his back, his legs hanging off the table, so as to have a better command of the parts. A common straight knife will be necessary to make the external incision; after the opening is made into the sac, a director is required in dilating it. The French use a winged director to press down the intestines from the way of the instrument, by which the wound may be dilated with greater security; they also use a concealed bistoury for dilating

the abdominal ring. Some dilate the sac with crooked scissors, which are very bad on all occasions. There is an instrument described by French surgeons for dilating the ring, to prevent the necessity of cutting it, by stretching it. This is entirely speculative, and must have been contrived by one unacquainted with the structure of the parts; for being composed of tendinous fibre, it is perfectly inelastic; and if the wound is dilated by this, it is merely by laceration; therefore it is better to use a knife, with a button at its end, which is very convenient for dilating the sac or ring; and if the knife is made concave it will be more convenient. The best director is the finger. Therefore, a common dissecting knife, and a knife with a button on the point of it, will be sufficient. The incision should be commenced at the upper part of the tumor. In a common bubonocoele the tumor extends above the abdominal ring, a little obliquely upward and outward. The incision should be begun at the top of the tumor, and extending downwards, that you may have a perfect command of the sac and its contents, bringing them all in view, that you may determine with greater accuracy how to proceed. By this incision the fascia is exposed which covers the abdominal ring and sac, which fascia should be divided; this has been frequently mistaken for the hernial sac. Having thus made the ring so distinct by the first incision that you can feel its edges when the parts are thus exposed, and you have opened the fascia which covers the hernial sac, you cut into it, which should be done with the greatest caution, otherwise you may wound a portion of intestine situated within the sac; but there is most commonly a quantity of serum interposed between the intestines and sac, so that you are generally safe; but as we are not always sure of this we should proceed with the greatest caution, and carefully dissect through, fibre by fibre, till an opening is made in that part; and if the hernial sac is not so much on the stretch but that you can pinch up a part, it will be done with the greatest safety. Sometimes, from inflammation, the intestine is adherent to the sac, and may happen to be so at that part you are opening; this will be again attended with a good deal of difficulty, for by the immediate union of the parts you will have a difficulty in distinguishing which is intestine and which is the sac; therefore, in these cases, having dissected with the greatest caution, you find you cannot get in at that part; you then try another, and in the part situated inferiorly you will be more likely to succeed than at the abdominal ring. Under these circumstances, having tried unsuccessfully about

the middle of the sac, I would then make an incision at the most inferior part; having dissected on with great caution, probably as soon as you get through, a bloody-like serum will pass out if there is water in the cavity; if the serum escapes, you introduce the finger, taking care that nothing is interposed between the finger and sac; then with a curved knife carry it along the sac, and dilate it upward; it need not be dilated quite up to the ring, as it opens the cavity of the abdomen. Having thus dilated it, expose the contents, which should be next carefully examined, whether intestine or omentum, or both, to see if any gangrene has taken place in any part. If the stricture is situated within the abdominal ring it will then be necessary to carry the knife between the sac and ring, and dilate the ring a small way, a little obliquely upward and outward, as much as will admit of your readily passing the finger into it. Having dilated thus much, then carry your finger up towards the orifice of the sac; and if you can carry it into the cavity of the abdomen, you are then to attempt a reduction of the parts. If both intestine and omentum are in the hernia, you try the intestine first, being most easy, which having returned, you then replace the omentum. When the parts are returned, the integuments on the outside may be brought in contact with each other, making two or three ligatures, which may be supported with slips of sticking plaster. The patient should be carefully laid down on his back, in an horizontal position, not with his shoulders elevated, till some degree of union has taken place.

There are many obstacles to the immediate reduction of the parts: 1st, adhesions, which arise very frequently between the omentum and hernial sac, or intestines and sac; either of these may produce adhesions; or, from preceding inflammation long before, old adhesions may have formed. In recent adhesions, sometimes the attachments are so slight, that you may readily separate them with your fingers; but when more firm, a knife will be necessary. If the omentum is adhering to the sac, we may make more free with it than the intestine. A large portion may often be removed with great safety; that portion may be removed which is adhering immediately to the hernial sac, and the remainder returned. However, we had better take away no more than is absolutely necessary; for the higher up, the larger are the branches situated within it, and a ligature on the omentum is unfavourable, for its strangulation by ligature may produce the symptoms of strangulated intestine; it may produce inflammation, which may extend along its substance; or if the ligature gets

into the abdomen it may cause a general inflammation of the cavity. If intestine adhere to the hernial sac it should be separated with great caution, for we must avoid wounding the intestine, or even cutting its coats. To remove this it is better to dissect off a small portion of the hernial sac adhering to the intestines, than endanger the cutting of the intestine itself. Also, they are sometimes found adhering to each other, and not to the sac; when this is the case, they form such a bulk of parts, that if a large opening is not made they cannot be replaced; for when the intestines adhere from inflammation they must be thrust in all at once. This requires a larger opening than we should wish to make, but is sometimes absolutely necessary; this renders the operation more dangerous, on account of the large aperture to be made into the abdominal cavity. Another great impediment to the return of the parts is that of large portions of omentum adhering at the orifice of the sac. Also, gangrene having taken place of the omentum, which often arises from patients not submitting to the operation so early as they ought to do. If the omentum, it may be removed; but in this it may be sometimes difficult to discover whether gangrene has taken place or not, especially if it has but just become mortified. To determine whether it is a part which may be safely returned or not, after you have taken off the stricture above and spread out the omentum, you may press the blood into the abdomen. If you find more blood returning into the veins, you may be sure circulation is carried on, though languidly, and if returned into the abdomen, it would go on as freely as before; but if no circulation is observed, so much as is defective should be removed, until the edges bleed; the remaining part should be returned into the abdomen; a ligature should be made on each of the bleeding vessels. You return the omentum into the orifice, leaving the ligatures on the outside. If the intestine is mortified, we should confine that portion of it to the orifice, that the contents may be discharged from the wound, which, if effused in the abdomen, would produce general inflammation and symptoms of irritation, and thereby speedily be fatal. The danger is from delaying the operation and exposing the abdomen. To prevent the intestine being drawn into the cavity of the abdomen, a needle should be passed round the mesentery, near the intestines, where it is gangrenous, and the needle carried through the integuments situated over the ring; thus forming a kind of artificial anus, in which state patients have often recovered, and in which they have lived a great num-

ber of years afterwards in tolerable health, only with the inconvenience of being under the necessity of wearing a great deal of tow to keep themselves clean. However, in some cases of gangrene of the intestines, when but of small extent, union will take place between that and the edges of the wound. If it be only a small portion of the side of the intestine which has sloughed, the principal part of the diameter of the canal being preserved, there will still be room enough for the contents to pass onward without much inconvenience. Some surgeons have proposed cutting off all the mortified parts, and introducing a cylinder of card and sewing the intestines together. I believe this is a very speculative operation, and very little probability of its being attended with success, for it would be very likely to produce general inflammation of the cavity.

Usually, after the operation has been performed, the patient becomes easy, and all the symptoms of strangulation immediately cease; but sometimes they have continued as violent as before. In all such we may suspect the operation has been incomplete, viz., that it has been only apparently performed, where the surgeon has thought the ring the only impediment to the return of the hernia, the patient has continued to vomit, because a portion of intestine situated within the sac was strangulated. We should, therefore, during the operation, see that all is free above; that there are no membranous bands situated within the orifice, by which the intestine is strangulated. After the operation, if symptoms should continue or return, the wound should be opened and the sac examined, passing the finger up to ascertain if the intestine be free. Also, more contractions than one may have taken place in a hernial sac, which, in cases of strangulation, should be dilated throughout their whole extent, be as many as there will, till you have a free communication with the abdominal cavity. It has been proposed to perform the operation without opening the hernial sac at all, from the idea of the greatest danger of the operation consisting in the exposure of the abdominal cavity. In many instances the impediment arises from the narrowness of the orifice: and it is necessary that the sac should be open, and the orifice dilated. Also, great danger will arise from our not being certain of the state of the parts within. If there be any adhesions within, there will be an insuperable impediment to the return of the contents. If gangrene has taken place, though you can return the contents into the abdomen, it will be with the utmost hazard to the patient's life.

After the operation, the wound should be treated like any common wound. Heal-

ing goes on very favourably; and after the cicatrix has been formed, it will be necessary to wear a truss for some time, to keep the parts supported.

Hernia congenita.—In this the intestine or omentum and testis are both situated in one common cavity. The difference in this from the former is, that it exists from birth; the other occurs afterwards. Thus the appearance of the congenital hernia will be similar to that of other herniæ in most respects. On examining the tumor, the only variation we shall find is, that the testis will be blended with the contents of the hernia. That the testis is not to be felt at the bottom of the sac, is very evident in common hernia. The treatment of this, and the operation, will be the same, excepting that we should not dilate the sac to the bottom, but leave so much undilated as will cover the body of the testis, and form a complete tunica vaginalis of that part. This will be attended with the advantage of its collapsing round the testis, which will prevent its being inflamed from exposure. Congenital herniæ are frequently not apparent for many years after birth in patients who themselves never had any suspicion that they had a hernia. When grown up, they have a hernia formed, which, on examination, is found to be congenital; as in one patient on whom I performed this operation, when about 18 or 19 years of age.

We have another variety in the bubonocoele to point out, which is that of the sac: though it comes through the abdominal ring, yet it is situated differently with respect to the epigastric artery to what the sac is in common hernia. I have met with two cases where the sac, instead of taking the course of the spermatic vessels, has come from the abdomen, from the inside of the epigastric artery; the epigastric artery was situated between the spermatic vessels and the sac. In which case the orifice of the sac must be opposed to the orifice of the ring, and the epigastric artery be on the outside. This variation requires some difference both in the application of the truss and in the operation. In such cases the pad of the truss should be applied more immediately on the ring, instead of obliquely on the outside, as in common cases; but then to do this it is necessary to point out the difference of these herniæ in the living subject from that in the common situation, which may be known in two ways. If the hernia has descended, and the sac is distended, you will see no tumor above the ring; it immediately terminates at the ring; whereas in common hernia the tumor is extended on the inner side of the tendon for some way upward. But here the orifice of the

sac is opposite to the ring. Provided the hernia has not descended far, or in a very inconsiderable degree, it may be known by the manner in which the descent takes place. If a common hernia, and you desire the patient to cough, it will raise the finger in the descent. If a hernia of this kind, by making pressure above there, you cannot compress the sac at all, and it will descend as easily as if no pressure was made. By thus attending to the manner in which the hernia descends, you may determine whether it is in the common or this unusual situation. The difficulty will be in the manner of applying the truss. In the operation in this case you should not dilate the hernial sac so high up as the other; only an inch above the ring, leaving an inch undivided. If you slit it above, the cavity of the abdomen will be more exposed, and the patient's life be in great hazard.

I shall next relate a few extraordinary cases of *bubonocoele*, which will serve to illustrate this subject.

A patient of Mr. Chandler's, in this hospital, was brought in one evening with a strangulated hernia, which he had laboured under for some days; he had extremely severe symptoms before he came into the house, as hiccuping, &c. From the feel of the tumor, there was reason to believe gangrene had taken place. In performing the operation, on laying bare the part, a large portion of the intestine was found in a gangrenous state; the fæces passed out at the orifice of the wound, also, from the anus. It was supposed at the time of the operation that the whole circumference of a portion of the intestine was in a gangrenous state. This excited the curiosity of many practitioners. After he had continued in this state for some weeks, the intestine, which was exposed at the orifice of the wound, became everted, projecting outwards, forming a kind of prolapsus, and a pretty large portion was at length forced out of the wound. As soon as the inversion had taken place, there was no discharge by the anus. He continued in this state for nine years in this hospital, and was under the necessity of covering the intestine with a large pad of tow to receive the fæces. When the part was exposed, there was an excellent view of the peristaltic motion of the intestine, which was at all times going on in that part: it was a florid surface, being the internal surface that was exposed, which turned outward. He died in the hospital; but two or three years before that event he had a hernia form on his left side. On examining the patient after death, you could pass the finger through the everted portion, under which there was another opening, which went into the cavity of

the abdomen. There were three openings externally—two in the colon, formed by sloughing, and adhesions subsequently taking place. The rectum was larger than usual, which was owing to a quantity of white limimentous substance collected there, and found throughout the whole large intestines, which seemed to be the secretion of the intestines themselves. This being secreted, kept accumulating in the rectum, and not being stimulating in itself, and there being no stimulus from the bile, &c., was not evacuated.

There are some cases of strangulated hernia in which there is so little appearance externally, that patients have been suffered to go on in that state without any operation being performed, or the disease suspected till it terminated fatally, as was the case with a patient in this hospital, who was supposed by the physician to have the iliac passion, the symptoms being exactly the same: this man died. On opening the cavity of the abdomen, no tumor appeared externally; there was inflammation within, and a small portion of the intestine going into the orifice of the sac, half of which was situated above the ring, in which portion a small fold of intestine was contained, and therefore had escaped notice; however it was sufficient to occasion the death of the patient. Mr. Else examined the patient, and found a little fulness, but no appearance of strangulation. On examining the body, there was found a hernial sac on the right side, similar to that on the left, with a very small fold of intestine situated in the transversalis abdominis. This shews the necessity of a cautious examination of all patients who have the symptoms of iliac passion: every part where a hernia can exist should be carefully examined, and if there is one, we must proceed accordingly. If a patient has a hernia, and if apparently returned, the application of a truss should give him great pain, it should be discontinued. The patient should wear a truss after the operation, as the sides of the sac seldom adhere, and the descent is generally easier than before.

Cruval hernia.—The situation of the sac in this species of hernia is immediately under Poupart's ligament, a little to the inner side of the large vessels (epigastric and iliac), passing down at the anterior side of the femoral artery: when the sac is somewhat enlarged, it is found extending over the femoral artery. This hernia is usually very small, so as only to appear like a lymphatic gland a little enlarged, and thus is difficult to discover; for posteriorly it is covered by muscles which will not easily yield, and anteriorly

by a strong inelastic fascia, which is binding it down. When it arrives at any considerable extent, it must be from the pressure existing for a long time. Hernia situated in this part is discoverable by the usual appearances of hernia in other places; as pressing the tumor, and desiring the patient to cough, when it gives an undulating stroke. In a case of this kind, if reducible, it should be returned. The patient should be laid in a horizontal position, the pelvis raised, the thigh of that side drawn up towards the abdomen, and the knee turned a little outwards, which relaxes the fascia. When returned, a truss may be applied immediately over the orifice; and as that will be situated very near to the orifice of the scrotal hernia, the pad of the truss should be applied to the same part—viz. just where the epigastric is coming off. When irreducible, little can be done. It is a part very unfavourable to make a moderate degree of pressure to prevent its increase; if you cannot reduce it, you cannot apply a truss, and you have not, in this instance, an opportunity of examining what the contents are, as in herniæ of the groin or scrotum.

If this hernia becomes strangulated, the symptoms will be as in others; and when other means have proved ineffectual, the operation should be proposed, which is attended with a great deal of nicety, from the situation of the vessels, the danger of wounding the epigastric artery in females, and both the spermatic and epigastric in males.

The external incision should be made in the direction of the tumor as far as it extends, beginning a little above Poupart's ligament and extending quite to the inferior part, a little obliquely inward to the inner part of the thigh; carrying it carefully through the fascia, which will be found covering the hernial sac. We next open the hernial sac with very great caution, for fear of wounding the intestine. A very small aperture is to be made into the inferior part, laying open the hernial sac up to Poupart's ligament: thus you get a view of the contents. The next attempt is to return the protruded parts; for it generally happens that the edge of Poupart's ligament is so pressing on the sac as to prevent the return, and which occasioned the strangulation; therefore they cannot be returned till the stricture is taken off by dividing Poupart's ligament, which is attended with danger, on account of the vessels as before said; for if you introduce a director, and slit it upwards, the vessels are passing so close underneath that you are in danger of wounding them. You may divide it safely by making a small opening into the

tendon a little above the vessels, in the direction of its fibres; then carry the director down to the under part of the ligament, bring it underneath, whereby we get the director between the ligament and vessels, whence it may be safely divided. If there should be left any fibres below still undivided, the director may be carried under these as before, which will give so much room that the parts may be very easily returned. Having thus divided the ligament, you are to return the hernia into the abdomen. If you find any difficulty, you should introduce the finger into the sac, to ascertain that the orifice is not contracted; if so small that the hernia is not readily reduced, a blunt-pointed knife should be introduced, and the orifice dilated with great caution, for fear of wounding the vessels. The French instrument, invented for dilating the ring, might here be useful, as the part is membranous and not tendinous. The danger in the operation is not so great in the female as in the male, and much oftener required in the former; as Poupart's ligament in females is about an inch longer than in men. Not unfrequently the tumor in this hernia is so small as to remain unnoticed by the patient or surgeon; therefore a patient may pass many years with a crural hernia undiscovered. Symptoms of strangulation may take place, which may be supposed to be only those of the iliac passion; and being treated as such, the intestines not being extricated, the patient will usually die; therefore this is a case of hernia we should examine with the greatest caution. In all cases where there are symptoms of strangulation, though we do not absolutely discover a tumor, yet if the patient complains of pain on pressure in any one part where herniæ are usually situated, we ought to operate, where the symptoms have gone on so far as to require the operation, by making an incision on the part, carefully dissecting down, to see if there is a hernial sac situated there; for the fold of intestine may be so small as not to be felt through the integuments.

Umbilical hernia, or *exomphalos*, is much more common in women and children than in men. In women, frequently from the distension which the abdomen undergoes during pregnancy, the navel, being a weak part, a protrusion takes place there; also in new-born infants, from violent exertions, as crying, &c.;—sometimes in men, but mostly in those who are become very corpulent. In these cases, where the hernia is in a reducible state, a spring truss should be adapted to make pressure on the part; but in children this is very inconvenient, for, by frequently wetting themselves, the spring of the truss soon becomes

rusty, and does not perform its office; also they cannot bear the pressure. In such it is more convenient to apply a piece of cork, cut round, and nearly as large as the aperture, dipped in wax; it should be applied on the side of the aperture, so as to press the integuments inwards; over which put some sticking-plaster, of a circular form, so as to make pressure on the part. After a few months this may be left off, when no further protrusion will take place. But in those who are older, this pressure made by sticking-plaster will not be sufficient to resist the action of the muscles; therefore a well-constructed truss will be necessary. In women, these ruptures are often irreducible, from their being apt to conceal them, and adhesions having taken place, and very frequently from omentum, which remaining there a length of time, undergoes an alteration in its figure, so as to prevent its return. In an irreducible hernia a pad should be formed, just to receive the part, merely to prevent its increase. If in this strangulated state, and the usual means are ineffectual, the operation will be necessary, which consists in making an incision throughout half the length of the tumor, or a little more; it may be begun on the upper part of the tumor, and extended downwards. It has been observed in these cases, that there is no hernial sac, which I believe often happens; it being surrounded by little more than a dense cellular membrane.

When the sac is exposed, whether of peritoneum or condensed cellular membrane, it should be carefully dissected through, then carefully dilated towards the orifice, where it communicates with the cavity of the abdomen: having exposed the contents, they should be returned without any further dissection of parts; if the orifice is so tight as to make any firm pressure it should be dilated, which will be best done, not by cutting through the hernial sac, but by introducing a blunt-pointed knife between the sac and surrounding tendon, and dilating it as far as is necessary for reducing the parts. The patient here should also wear a truss some time after the cure. In case of mortification, we should proceed in the same manner as in scrotal hernia. In cases where there should be such firm adhesions as to be inseparable by dissection, we must proceed in the same manner as was recommended in bubonocœles. Mortification not unfrequently takes place in the contents before surgical assistance is called for, particularly in women.

Ventral hernia.—Where a protrusion is formed between some of the tendinous and muscular fibres of the abdomen, it will appear exactly the same as *exomphalos*, formi-

ing a similar tumor, and the treatment will be the same. The form of the tumor is not so regularly rounded as the umbilical, the parts projecting under the integuments, and being of a firmer consistence. In these cases, where the operation is necessary, we have only two parts to attend to, in dilating the orifice where the stricture is formed; these are the epigastric artery and ligamentum rotundum, which last we should avoid dividing—as it is not at all times even in an adult in an unperforated state, sometimes remaining open during life. Therefore, as there are some instances of the umbilical vein remaining, on that account the ligamentum rotundum and umbilical vein should not be divided.

Hernia foraminis ovalis.—Forming a tumor in *perinaeo* by the side of the thigh. I have never met with but one case, and that was in Paris; it was about the same size as we usually find the crural hernia. Where it is very small we should not be able to discover it. However, where it is of long continuance the protrusion may become so large, and the tumor also, as to be very evident. Mr. Pott informed me of two cases which came under his inspection, where the tumors were very conspicuous. In a case of this kind, if reducible, a bandage should be contrived to make pressure on the part in *perinaeo*. If strangulation should take place, the operation,—which will be performed with greater difficulty on account of the situation of the obturator artery,—the sac being laid bare, should be carefully opened, and the finger carried up to the obturator ligament, which should be very cautiously divided. In this case, I can hardly direct how the ligament should be divided. I should rather suppose that the vessels go to the under side of the sac, as the ligament is situated below; if you divide it downward, you would be liable to wound the obturator artery, therefore before you divide the obturator ligament, you should feel with your finger in different parts, and probably by the pulsation you might discover the situation of the obturator artery, and thereby avoid wounding it.

Hernia cystica is formed by a protrusion of the urinary bladder, and is not a case where there is a probability of strangulation arising, as there could be nothing accumulated but urine, and this by pressure being made on the outside, might be carefully carried back, and the bladder disengaged. Mr. Pott has given two cases of this kind, one in a boy, who had a hernia of this description; with a hard substance, situated within which was a calculus. In this case he made an incision over the tumor; on the projecting portion of the

bladder, he made a ligature, thus including the calculus, which portion he cut off*. This preparation I have seen; the stone was about the size of a small walnut. In dissecting this carefully there was an appearance of something like an artery.

Two other herniæ remain to be described, that of the *ischiatric notch* and the one situated in *perinaeo*, passing between the vagina and rectum. These are situations, which, from the size of the cavity through which they pass, do not subject the parts to strangulation. If there should be any, you must lay the parts bare, and proceed according to appearances. Having met with no cases of this kind, I cannot direct you.

In books which treat of herniæ it is usual to mention their radical cure, for which several different methods have been proposed. This can only consist in obliterating the hernial sac, or that part of the orifice through which they protrude. This in scrotal hernia has been proposed in various ways; first, by applying caustic to the part: this will be exceedingly hazardous, as we cannot always regulate how far the caustic shall extend; if through the posterior part of the sac, it would probably destroy the spermatic cord. Another mode proposed is that of making a ligature on the hernial sac; but from the close union of the spermatic cord to the posterior part of the sac, it seems impossible to inclose the sac without the cord. In all these operations it has been proposed to do it below the ring, as there is often a large portion of the sac above the ring, in such cases the hernia would not be cured. I believe some empirics, as related by Heister, were in the practice of castrating the patient at the same time. It was proposed once by the Parisian surgeons to cure the hernia radically by performing the operation on patients who had no strangulation, from an idea that by this means the sides of the sac would unite with each other, and the patient have no return of the complaint, but this plan was not successful; the sides of the sac did not unite, and in some cases the patients died, hence the practice was soon discontinued. So far as has hitherto been done, no such mode of curing the complaint can be adopted with any propriety. The only mode of producing a radical cure would be wearing the truss for a considerable length of time, so as to obliterate the opening, or so far diminish it as for nothing further to descend.

CLINICAL LECTURES ON MEDICINE,

Delivered at the Meath Hospital, Dublin,

Session 1837-8,

BY PROFESSOR GRAVES.

LECTURE III.

Case of Typhus Fever with general Bronchitis—Treatment in first stage; in second—Apparent Anomalies in this Treatment—Morbid Anatomy often studied in a wrong manner.—Observations on the Causes of Pectoral Symptoms in Fever; on the latent Period of Morbid Poisons; on Double Diseases; on Hereditary Diseases.

GENTLEMEN,—Allow me to call your attention to the case of Mary Lynch, admitted on the 16th of November, labouring under well-marked *typhus*. She is a servant, married, 38 years of age, of a full habit and sanguine temperament. About eight days before admission, she was attacked with symptoms of fever, accompanied by pains in the loins, shoulders, sternum, and left mamma, so violent as to interfere with respiration; she had also tenderness of the abdomen, particularly at the epigastric region, frequent eructations, vomiting, urgent thirst, harassing cough with viscid sputa, and total loss of rest. About the seventh day, maculae, of a bright red hue, some large, some smaller, and clustered like measles, made their appearance in great abundance. As the belly was full and tender, she got mild aperient medicine, and it was leeches.

On the evening of the 19th she appeared much worse, lying on her back, moaning, unable to move without assistance, her face flushed, skin of a burning heat, and eyes much suffused; her tongue was furred, pulse 130 and weak, and respiration laboured—about 40 in a minute. No dulness on percussion existed, but loud, sonorous, and sibilous râles were heard all over the chest, particularly in the anterior regions. It was clear, therefore, that our patient had two distinct diseases—spotted fever and bronchitis: the former had commenced with symptoms of unusual violence, and the latter was of a formidable nature, engaging a vast number of the smaller bronchial tubes, and interfering most unfavourably with the breathing. In short, gentlemen, we seemed called upon to treat, in the same individual, two affections of opposite characters—the one inflammatory, and requiring antiphlogistic measures—the other exhibiting a strong tendency to putrescence, and, at the actual stage of her illness, rapidly giving rise to sinking and exhaustion.

Emergencies of this kind require much

deliberation, and are calculated to excite strong feelings of embarrassment and doubt in the mind of the practitioner, for he possesses no general rule to direct—no theory to indicate the treatment. Under such circumstances, how happy do we feel if enabled to call to mind some case of a similar description, where we had observed the effects of treatment with anxiety, and noted them with due accuracy; how cheerily does the light of the past then dispel the obscurity of the present; and how thankfully do we accept the guidance of recorded facts, without whose aid all would be uncertainty and confusion!

Were we, in treating our patient, to direct our attention chiefly to the extensive bronchitis, and prescribe cupping, leeches, blisters, calomel, squills, digitalis, or ipecacuanha? or were we to strive rather against the general than the pectoral ailment? The following considerations seemed capable of affording a solution of these difficulties. In the first place, we had to attach a proper degree of importance to the period of her disease: the spotted fever had already lasted eleven days, after which the symptoms of reaction usually begin to decline, and are followed by a rapid and alarming prostration of strength, requiring the administration of stimulating medicines and a more nutritious food. But here the question occurred, would not nourishment and wine increase the bronchial inflammation, and might they not augment the amount of local disease, by inducing pulmonary congestion, or even pneumonia?

Dr. Stokes, who, during my temporary absence, had the charge of this patient, evinced his usual skill and judgment, and justly regarding the fever the principal disease, he determined to give wine and chicken-broth, with a mixture containing carbonate of ammonia. She got one bottle of port-wine in the course of the next twenty-four hours; while an attempt was made to relieve the chest by dry-cupping, blisters, and small doses of hyoscyamus and ipecacuanha. The same medicines were continued on the succeeding day, but the wine was diminished about one-fourth. Let us now examine this patient, and ascertain what effects have been produced by this treatment, now continued forty-eight hours. You observe, gentlemen, a striking improvement: the fever has a much less threatening aspect, the maculae have nearly disappeared, the tongue become much cleaner, skin more natural, belly soft, sleep tranquil, and the pulse has nearly fallen to its normal frequency. Such is the result of the treatment, as far as the fever is concerned; but what changes has the bronchitis undergone? Here the effect produced is most satisfactory, for, so far from increasing under

the use of wine, moderate nourishment, and carbonate of ammonia, the bronchial inflammation has notably subsided, — the woman's breathing is now comparatively free and calm, and she is less troubled with cough, while the sonorous and sibilous râles are rapidly becoming less distinct. It is our intention to continue the wine and ammonia, but in daily diminishing quantity, and I have no doubt that our patient will soon be able to do without them entirely*.

This case is well deserving of a more careful analysis. With respect to the fever, it was evidently accompanied, in its accession and first stage, by active congestion of the gastro-intestinal and bronchial mucous membrane. Had we been consulted during the rigors, or the first six hours, a bold use of the lancet would have cut short the disease; on the second day, at least during the first half of it, venesection would have been required, but in smaller quantity, and with the effect, not of stopping the fever, but of moderating all the most prominent and distressing symptoms; for the next two days, leeches to the epigastrium and sternum, frequently applied, six at a time, would have powerfully contributed to produce a more natural state of the gastric and bronchial mucous membrane: unhappily the case was neglected before its admission into our ward, and then we were unable to proceed boldly with depletory measures, as the maculæ were very abundant and the fever had arrived at its ninth day. But here some one will observe, inflammation of a mucous membrane must be treated on the same principles, no matter whether it occurs in the commencement, the *acmé*, or the decline of fever: in every case it must be met by depletory measures, modified, indeed, as to their activity, by the period of the disease and the strength of the patient; *but still depletory they must be*; and in no case are stimulants allowable — in no case wine and nourishment admissible. Gentlemen, there seems to be much that is reasonable in these observations, and they obtain additional confirmation from the testimony of those who assure us, that in persons affected with typhus accompanied with pectoral and abdominal symptoms, such as we witnessed in Mary Lynch, and in whom the disease proves fatal, the post-mortem examination always exhibits indubitable evidence of inflammation affecting the mucous membranes in question; but I must confess that I am more inclined to rely on the effects of remedies as a test of the true nature of diseases, than on the evidence derived from post-mortem examinations. The manner in which a living tissue conducts itself when

acted on by food or medicine, is with me of greater value in determining the nature of a disease affecting that tissue, than any appearances observable in it after death. Suppose that Lynch had died just as we had ordered the wine, broth, and carbonate of ammonia, and suppose her chest and abdomen examined in a few hours after, then I have no doubt that appearances enough would have been detected in the stomach and bronchial tubes to convince you of the existence of mucous inflammation, and you would have been apparently justified in strongly condemning our practice. This I say advisedly, and with what intention? To decry the utility of morbid anatomy? Certainly not. I cannot, indeed, now discuss the general question as to the manner in which morbid anatomy should be prosecuted, in order to render it useful to practical men; but this much I may be permitted to remark, that in the hands of some of its most zealous cultivators, it has degenerated into a system in which the facts discovered have not been arranged and valued according to their obvious bearings, but have been made the foundation of much useless pathological mystification; in truth, it is my fixed opinion, founded on no small opportunities of observation, that in fever especially much error and uncertainty still attend the interpretation (if that expression may be used) of *post-mortem* appearances, and consequently great mischief has resulted from rules of practice derived rather from the dead-room than from the clinical ward.

But to return to our patient. Her case teaches you how, in the progress of typhus fever, the state of the mucous membrane of the stomach and bowels alters, and how its vital energies vary as the disease advances; for we see wine required, — we see it borne, — nay, useful, not only to the system at large, but to the alimentary mucous membrane in particular, on the eleventh day of fever, in a case where it would have been injurious, perhaps destructive, at an earlier stage; and mark, that it was thus useful, *even although all the symptoms which might be justly considered as contraindicating its exhibition had not entirely disappeared!* We learn from this that our feeble powers are incapable of appreciating the meaning, the intensity, or even, in every case, the identity of particular symptoms. We must, therefore, never sacrifice general views to individual indications, and, in fever especially, *we must study the whole man, and not any particular organ.*

I have long ago advocated the opinion that we may have bronchial râles generally diffused throughout the chest in fever, and yet the existing affection may not after all be true bronchitis. This opinion I put forward about seven or eight years ago in my lectures, but it did not attract the

* This patient perfectly recovered, to the no small astonishment of two foreign physicians, who were somewhat tinged with *Broussaism*.

attention which I think it deserves. I have over and over again seen fever patients, apparently labouring under all the physical symptoms of general bronchitis, with universal sonorous and sibilous râles, impeded respiration and cough, and yet, if a crisis came on, and a favourable turn in the general state of the patient took place, I have seen all the symptoms of pulmonary derangement disappear in the course of a few hours without any treatment. The present form of fever is not a good one for observing this remarkable change, but in the fever of 1826 we witnessed it frequently. A patient in the morning, labouring under a threatening array of apparently intense pulmonary symptoms, might be seen in the evening with diminished pulse, calm respiration, and scarcely a trace of cough. This convinced me that true bronchitis is not present in every case of typhus, where you have difficult respiration, cough, and sonorous and sibilous râles. Recollect what the effects of fever are on the general system. It renders the skin hot and dry, furs the tongue, parches the fauces, and alters the secretion of the intestinal canal, giving rise to constipation or purging. The digestive tube is generally in an unnatural state, and it is very probable that fever not only deranges the state of the skin, but also of the mucous membrane of the mouth, nose, throat, and alimentary canal. It likewise alters the secretion of the liver and of the kidneys; if the skin is altered in its physical characters, if its secretions are suppressed, and its temperature changed under the influence of febrile disturbance, surely it is not irrational to suppose that the mucous membrane of the bronchial tubes may be also changed in its physical properties, and that its surface may become unnaturally moist or dry, and its tissue engorged. Now, where the derangement extends to the bronchial tubes, we have some of the physical changes produced which accompany ordinary bronchitis, and consequently, *in cases of this kind*, we have cough, sonorous or sibilous râles, difficult respiration, and imperfect aeration of the blood, with purplish suffusion of the face; but this state differs from genuine inflammation in some respects, and in none more remarkably than in its mode of terminating. What happened in the fever of 1826? When a crisis arrived, in the course of two or three hours, the skin became soft and moist, the patient expectorated freely, and every symptom of cutaneous or bronchial derangement rapidly disappeared. In typhus, it is true, genuine bronchitis often occurs as a complication, and is to be treated as such; but it frequently happens that you will have to treat disturbance of the respiratory system, accompanied by cough, impeded

respiration, imperfect aeration of blood, and sonorous and sibilous râles, in fact, with a train of symptoms producing as much distress to the patient, and alarm to the physician, as if it was an attack of genuine bronchitis. This view of the subject explains a good deal of the apparent incompatibility of our treatment with the phenomena of the case before us. I do not mean to assert that it was wholly free from real bronchial inflammation, but I think I am authorized in saying that there is a state of the mucous membrane of the lung, in fever, characterized by cough, bronchitic râles, impeded respiration, and undue aeration of the blood; the essence of which is not true inflammatory action, but an altered vital condition, whose nature has not hitherto attracted the attention it deserves. If this be true, gentlemen, you perceive that as fever has in itself a tendency so to derange the bronchial mucous membrane as to reduce it to a state nearly allied to the inflammatory, this very tendency must, on the one hand, facilitate the production of true bronchitis in fever, and on the other, it must render the cure of true bronchitis more difficult.

While on the subject of pathology, allow me to notice one very important fact. In several instances I have observed that certain diseases, which seemed to have been lurking in the constitution, may suddenly make their appearance in consequence of the operation of causes apparently unconnected with the disease in question. This is not unfrequently observed in patients who have contracted syphilis,—have had genuine chancre, and received into the system a poison which will sooner or later manifest itself in the form of constitutional disease. A person in this state exposes himself to cold—gets an attack of shivering, followed by catarrhal fever, and next day, or the day after, the constitutional symptoms of syphilis appear. This, in some cases, appears very extraordinary to the patient himself. He had taken mercury, in all probability, irregularly and improperly;—thinks himself quite well, and now he is suddenly attacked with secondary symptoms. I have witnessed several cases of bad secondary venereal, in which the attack was traced to excessive fatigue, or a common cold. You will also meet numerous examples of an analogous fact among fever patients: examine them, and you will learn that, in a majority of cases, their disease arose from exposure to cold. One person fatigues himself by too much exertion in business, and gets an attack of spotted fever; another attributes his disease to over-anxiety; some to intemperance; and some to fright. In all these cases, it is very probable that the poison of fever has been

lurking for some time in the system, and has then been called into active existence by the operation of some sudden accidental cause—as fright, fatigue, intemperance, or cold. The same thing is seen in other diseases of a very different character.

Some time ago I attended, with Dr. O'Beirne and Mr. O'Flaherty, a young gentleman residing at the north side of the city, who, previously, had received an injury of the hand; after the accident, every thing appeared to be going on well, until one day he happened to be exposed to the inclemency of the weather, while in a state of exhaustion from too much exercise. He got a violent cold, which, in a few hours, was followed by all the symptoms of well-marked tetanus, of which he subsequently died. Here you perceive exposure to wet was followed by symptoms of feverish cold, and this, in its turn, called into active operation the disposition of tetanus, which lay, as it were, dormant in his system. I recollect another case of an analogous description, which occurred here soon after the battle of Waterloo. An officer of the 95th, or Rifle Brigade, happened to be bitten by a dog, of which, however, he took no notice, and the wound healed up kindly. He went home to see his family some time afterwards, and appeared in excellent health and spirits. It happened at this time his father was making some improvements in his demesne, and this young gentleman, who took much interest in them, was constantly engaged with the workmen. One day he fatigued himself greatly in cutting the roots of trees, and on the same night he was attacked with all the symptoms of hydrophobia. Here we have an instance of a fatal disease called into sudden activity by the influence of fatigue. Something similar is frequently observed in the case of Irish labourers, employed during the summer and autumn among the fens of Lincolnshire. During their stay in England they appear free from disease, but on their return home, if they happen to be exposed to wet, fatigue, or the derangements of health consequent on intemperance, they are very often seized with intermittent fever.

These facts seem to lead to the conclusion that poisons or morbid causes, capable of producing acute or chronic diseases, may remain latent in the human system for a very considerable period of time, and then be called into active operation by affections which, in many instances, appear to have little or no natural connexion with the diseases they usher in. A question here arises, whether, in many of these cases, the poison might not have remained dormant in the system, and its effects have passed away without ever manifesting themselves, had not the exciting cause come into play?

May it not happen that persons said to have been bitten by mad dogs have escaped in this way?—does it not often happen that many of us escape fever, although exposed to its contagion month after month?—do we not go on for years untouched, although subject every day to the imbibition of the poison?—and do we not, rendered bold by our impunity, consider ourselves, as it were, fever-proof, until some accidental cause convinces us of the contrary, by giving rise to a sudden and violent attack? Who is there that has not observed this repeatedly among the students attending a fever hospital? Now it would be interesting to know whether this holds good with regard to syphilis, and whether a person whose constitution has been tainted by the venereal poison, may not occasionally escape secondary symptoms if wholly withdrawn from all the usual exciting causes, such as cold, fatigue, intemperance, irregularity of life, and the like. I am persuaded that, in some diseases, particularly of an acute character, the poison may be taken in doses too small to produce the disease, without the aid of some accessory cause. The question is, can we come to the same conclusion with regard to chronic affections? Can not gout, scrofula, hereditary epilepsy, hereditary insanity, remain dormant in the system without ever appearing, if the patient be kept from all the ordinary exciting causes? May constitutions be infected with the poison of venereal from true chancre, and, by means of regular habits and temperance, occasionally escape secondary symptoms altogether? On a future occasion, when we come to consider the general pathology and treatment of syphilis, we shall resume the consideration of this interesting question.

There is another subject of much importance, on which I purpose to make a few remarks. I allude to what may be termed double diseases, or that state of the system in which two morbid causes are simultaneously in play. You will recollect I commenced with an example of this state, viz. the co-existence of bronchitis and fever; but there are many other diseases which may not only exist singly, but also in conjunction with others. Thus, to take an example from the class of cutaneous diseases, we may have syphilis and scabies, measles and small-pox, co-existing. We may also have measles and whooping-cough, mercurial erythema and syphilis; or we may have the constitution labouring, at the same time, under the combined operation of syphilis, scrofula, and mercury. In the same way you may have gout or rheumatism co-existing with other constitutional affections, or with local affections of various parts of the body. One of the complications of gout to which I directed the attention of the pro-

fession, in a lecture published some years since, is bronchitis. Dr. Wm. Stokes, in advertg to this complication, in his admirable essay on Bronchitis, has very properly observed that the effects of gout on local diseases have not been studied with sufficient attention. While on this subject, I shall mention a curious fact connected with the relation which gout bears to bronchitis. A young gentleman, aged 13, labouring under asthma of a very violent description, accompanied by bronchitis, was placed under my care. I employed numerous remedies for the relief of the asthma and bronchitis, but with little or no effect. Asthma is a disease of a very uncertain nature, and depending on a variety of causes; hence there is no affection which requires so many different and even opposite modes of treatment. I tried every thing from which I expected to derive the least benefit, but without success. Let me observe here that both this young gentleman's parents were gouty. About three weeks ago, shortly after his arrival in Dublin, while labouring under asthma in a very violent degree, sitting up in bed half the night, with loud wheezing, alarming dyspnoea, and great distress he was suddenly attacked with an acute fit of gout in the foot: he got, in fact, as regular an attack of podagra as ever I witnessed, which, having affected one foot and toe for some days, then attacked the other. From this time, however, the bronchitis and asthma wholly disappeared. He recovered in about three weeks from the gouty affection, and has remained quite well ever since. [This young gentleman continued free from asthma or bronchitis during the whole of the severe winter that succeeded, and is in good health at the present date, the 18th June, 1838.]

I lately saw a gentleman in whom the gouty inflammation subsided too quickly in the foot, and transferred itself to the pharynx and larynx, occasioning a constant hawking up of frothy mucus from the irritated throat, and a dry laryngeal cough, which gave him no respite night nor day. As long as this strange attack lasted the patient's condition was truly miserable; the irritation ceased as unexpectedly as it had commenced. Another fact connected with gout ought not to be passed over in silence. About five years ago, I saw a lady of an extremely advanced age, and whose father had died of hereditary gout; the lady in question never had any appearance of gout until she had attained the age of 82, when podagra first seized her violently, and visited her at least twice annually until her death. Now this case leads to many interesting reflections, and has an important bearing upon the curious but well-ascertained fact, that hereditary diseases often pass by one generation to reappear in the

following. Had this lady died before the age of 82, her children would have believed her to have been free from the hereditary taint, and would have wondered how the gout of the grandfather could have re-appeared in them, having spared their mother. This case justifies us, therefore, in concluding that the hereditary tendency exists in the generation which is spared, but is either not strong enough to start into action without the concurrence of certain favouring causes (which may not be present throughout the life of the individual), or is counteracted by other and opposing tendencies in the constitution.

CASE OF STRANGULATED MESENTERIC HERNIA.

To the Editor of the Medical Gazette.

SIR,

INCLOSED is a case of intestinal obstruction, which I believe to be of rare occurrence. The insertion of it, if you should deem it worthy, in your much respected journal, will greatly oblige, sir,

Your obedient servant,

ROBERT RANKING.

Hastings, Sussex,
Oct. 1838.

H. P., Esq., a gentleman, aged 66, of robust frame and temperate habits, was seen by me for the first time during this, his fatal illness, on the night of Tuesday, the 24th of July last.

Previously to this period his health has been so good as to dispense with medical advice, with the exception of an attack of enteritis nine years since.

He was much addicted to bodily labour, and employed himself daily in his garden the greater part of the day. On the above-mentioned day he had been engaged chiefly in removing earth in a hand basket, and as usual gave up work at 1 o'clock, to dress for dinner. At this time he drank a glass of beer, which, according to his own expression, fermented in his stomach, and was soon rejected. He, however, ate his dinner, but was not able to retain it. He at this time complained of some uneasiness in his bowels, but not sufficient to prevent his resuming his labour. This second exertion appeared to fatigue him, and he returned to the house with a recurrence of the uneasiness and vomiting. This subsided in the course of the evening, and he retired to rest feeling much relieved. I saw him at 11 o'clock,

P.M., and found him in bed. He expressed regret that I should have "taken the trouble to visit him, as he was much better." He did not complain of any pain; his countenance was natural, and pulse quiet and regular. The bowels had not been relieved that day, but had acted freely twice the day before, and were usually regular.

Considering that his symptoms arose from the presence of some irritating substance in the bowels, I gave him two calomel and opium pills, and a common black draught to be taken in the morning.

I visited him the next morning, and found that he had breakfasted, and that he felt, according to his own statement, nearly as well as ever. The medicine had not acted, but he expressed his belief that it soon would do so. After a conversation on indifferent subjects, he walked with me to the end of his garden, and begged I would not call again

unless he should send. I therefore did not see him again till Thursday, the 26th, about 2 P.M., when I received a hurried message that he had been seized with a recurrence of severe vomiting, attended with constant hiccup. I found the vomiting and hiccup incessant; the abdomen tumid, but without pain, even on severe pressure; tongue white; pulse 66, feeble and soft; countenance cheerful. There had been no evacuation from the bowels since the first attack of sickness.

As the case now assumed a serious aspect, I examined carefully for an explanation of the symptoms. No hernia could be detected.

I immediately threw up a copious injection of gruel, with *Ol. Ricini* and *Sp. Terebinth.*, which was quickly returned. I then directed the abdomen to be fomented, and covered with a mustard poultice, and gave him calomel and *Ol. Ricini*.

I saw him again that evening, and

E. Loop of intestine passing through the laceration.

found him much in the same state. No stool; abdomen tumid; no pain on pressure; pulse regular, soft, but feeble; vomiting and hiccup very severe. The same measures were continued, with the addition of drachm doses of the tartrate of soda in effervescence every two hours.

Friday.—Some abatement of sickness, otherwise in the same state. I again carefully pressed the whole abdomen, without causing the slightest pain. The injections were repeated, but were always checked after a certain quantity had been thrown up, when they were

immediately returned. Night arrived without the slightest relief being afforded. I visited him early on Saturday, the 28th, and found all the symptoms greatly aggravated; the vomiting was now evidently stercoraceous; hiccup distressing; body cool, and bedewed with clammy perspiration; pulse feeble. Still no pain. He was placed in a warm bath, and took small doses of *Ol. Ricini*, *Sp. Terebinth.* and *Tr. Opii*, every three hours: he was cheerful and confident of recovery at this time; but began to sink very suddenly, and died at 2 p.m.

Post mortem.—The body was examined 42 hours after death. Decomposition far advanced, especially over the abdominal region. Head not examined.

Thorax.—Adhesions of ancient date at the posterior portion of the left lung; the right side perfectly free; lungs themselves quite healthy; no fluid in pericardium; heart dilated in all its cavities, very flabby and much decomposed; some ossific patches in the arch of the aorta.

Abdomen.—Liver healthy; air infiltrated beneath its peritoneal coat, on its convex surface; gall bladder much distended by black viscid bile. Stomach of natural size; all its textures softened. Small intestines greatly distended; their coats softened, and of a dark colour; their vessels considerably injected. About half a pint of turbid serum in the peritoneal sac. The mesentery was so exceedingly soft that the mere act of raising the intestines was sufficient to rupture it. Much of this probably depended upon the advanced stage of decomposition. As yet we had not found sufficient cause for the symptoms; but upon tracing the intestines, we found at the lower third of the ileum a peculiar and complete strangulation. I removed the part for more patient investigation than I could at this time devote to it.

I found that the mesentery had been separated from its attachment to the under surface of the bowel for the space of an inch and a half. The loop thus formed was further diminished by the intestine taking a turn upon itself, so as to convert the loop into a figure of 8. Through one of these smaller loops a knuckle of intestines, six inches long, had passed, and become tightly strangulated. There were thus two distinct points of strangulation; one formed by the twisting of the intestine upon itself, the other by the passage of the knuckle of intestine through the loop. Both strangulations were so perfect that air could not be made to traverse them without great difficulty. The edges of this laceration of the mesentery were smooth, and did not exhibit any trace of effusion of blood. The intestines below the stricture were closely contracted and empty. Other abdominal viscera healthy.

The symptoms of this case were evidently dependent upon complete obstruction of the intestinal tube. The first attention was naturally directed towards the discovery of a hernia. No displace-

ment, however, could be perceived upon the most rigorous examination, and I was therefore driven to expect the next most probable cause for the symptoms, viz. intus-susceptio. The real state of the case certainly did not occur to my mind. I am not able to find any record of a similar kind of obstruction; the nearest approach to it being mesenteric herniæ, caused by the separation of one layer of the mesentery. One or two cases of this kind are mentioned, I believe, by Sir A. Cooper.

One remarkable feature in the case was the total absence of pain and all the usual symptoms of inflammation of the bowels, which the post-mortem appearances shewed to have existed to a great extent. Mortification had not ensued in any portion of the intestine; the greater part was softened and highly injected. That death took place antecedently to the occurrence of mortification was probably due to the feeble state of the heart, which was greatly dilated, and so much softened as readily to be perforated by the finger.

It is evident that no treatment whatever could have been successful, even had the true cause been known. The case, however, is instructive, inasmuch as it tends to extend the diagnostic history of intestinal obstruction.

TREACLE AS A DRESSING FOR BURNS.

To the Editor of the Medical Gazette.

SIR,

I HAVE read with great pleasure a paper by Dr. Greenhow, of North Shields, in last week's GAZETTE, on a new method of treating burns, and was forcibly struck with the coincidence of his practice and my own for several years past, varying only in the nature of the composition used. The want of uniform rules and safe means for the alleviation of human suffering in any case is a lamentable proof of the unsettled state of medical science, and there is no better example of this condition than in the treatment of burns and scalds, which has been for the most part empirical. Every person has his own peculiar practice, and emphatically speaks of its success: while "one person (as Dr. Greenhow observes) has advocated the use of cold and sedative applications,

another has extolled the efficacy of stimulating ones; and although, doubtless, much depends on the nature and extent of the injury, nevertheless there seems to be a want of some sound principle of practice, which, when once established, might be modified according to the exigencies of each individual case."

Raw cotton, sugar, and meal, flour, linseed oil, and lime water, spirits of wine and terebinthinate applications, have each had their separate votaries and zealous adherents, and yet none have stood the test of general experience. Professor Velpeau has divided burns into four stages: "first, simple rubefaction; second, vesication; third, destruction of the rete mucosum and first layer of true skin; and fourth, where a part of the whole layer of the skin is converted into an eschar." In addition to these, Baron Dupuytren, in the "*Leçons Orales*," which were published in the *MEDICAL GAZETTE*, vol. xiii. page 410, very properly recognises a fifth and sixth stage, where the muscles and tendons are burned, and vitality partially or totally destroyed. M. Velpeau's practice consists in applying strips of diachylon plaster around the injured limb in all the four stages of burns, after the manner recommended by Baynton, in the treatment of ulcers, removing them only at stated intervals, according to the exigencies of the case, which, by making a gentle and uniform pressure on the injured limb, and excluding the atmospheric air, materially diminishes suppuration, and in some cases entirely prevents it. Dr. Greenhow's plan consists in melting over the fire the Ung. Resin. flav. cum Ol. Tereb., and applying with a brush or bunch of feathers the composition so heated over the affected part, so as to form a complete coating over the burnt surface; and this practice, he states, has been signally successful in preventing suppuration, and in preventing the bridges which form during cicatrization, and disfigurement of the countenance. Now, in the first and second stages of burns and scalds I prefer the external use of treacle, which, from its simplicity, readiness of access, comparatively little expense, and almost uniform success, cannot fail to recommend itself to every one. Before trying the use of treacle I had attempted cold water and spirituous dressings, protected with oiled silk, linseed oil, and lime water, but frequently failed in prevent-

ing the smarting burning pain arising from the sensitive state of the cutaneous nerves, till it occurred to me that treacle, being a tenacious, plastic, refrigerant liquid, when pure, would effectually exclude atmospherical air, whilst it would astringe and cool the inflamed part. The last case I used it in was attended with marked success; since then I have tried it in 65 cases, and with variable effects. Three things are necessary in its employment: first, that it should be free from sand, splinters of wood, and dirty water, with some of which it is commonly adulterated; secondly, that it should be spread upon fine bleached calico without any asperities from uneven threads; and thirdly, that it should be cold. When used in this way I have frequently seen the most agonizing pain immediately cease, and turgescence of the inflamed skin diminish. In mild cases one dressing will suffice. Where vesication is large and extensive I have frequently evacuated the contents by means of a fine pointed needle, avoiding laceration of the detached skin; but oftener prefer a thick coating of the treacle upon the part, and afterwards enveloped with cat [?] paper, which, from the delicacy of its structure, will sooner tear than suffer the raised epidermis to be detached. In common cases, where the burn is slight, I spread the treacle upon fine calico, and apply it after M. Velpeau's plan around the affected part. Where calico of the description mentioned is not to be obtained, I use paper with similar results.

Where destruction of the skin has taken place, and the part has become a sore, I have thought treacle promoted suppuration and retarded the cure: in these cases I have used the Ung. Plumb. C. of the new Pharmacopœia, after M. Velpeau's plan, with great advantage. When the burn is of the fifth and sixth kind of Baron Dupuytren, I first detach the eschar with spirits of turpentine and charcoal formed into poultice, and repeated till the line of demarcation sets in, when I use the plaster as in the fourth kind, and give internally the Inf. Sarsap.; and should there be no energy in the part to granulate, or throw off the slough, the Potassæ Hydriod. has been of essential service. When an ulcer of large size forms after the slough has separated, the mucous surface of the alimentary canal sympathizes, and the mucous follicles of the large intes-

times become inflamed, and if not judiciously attended to, soon ulcerate. Two fatal instances have latterly occurred in my practice, which fully verify this conclusion. In such cases, after seeing the bowels are divested of scybala, should ulceration have commenced, I have found small doses of ipecacuanha, mucilage of acacia, and nitre, with the free use of the superacetate of lead and opium, in the proportion of three grains of the former to one of the latter, very beneficial. Burns occasionally happen to persons labouring under eruptive diseases, which prove a formidable obstacle to the cure, and often defy the best judgment. In such cases, after the inflamed skin has subsided, and the part is suffering more from the eruptive disorder than the burn, I apply the hypo-chloride of sulphur ointment, and give internally Plummer's pills, which seldom fail after a fair trial. In conclusion, when suppuration can be prevented it is very desirable; and I have seen some rare cases, where the injury appeared very great, get well in the course of a few days, under the treacle dressings, when aided by a sound constitution. The practice certainly bears great analogy to that of Dr. Greenhow's, and I have found it to supersede any other which I have tried; but after very extensive observations and practice, in candour I must confess I am not so sanguine in the invariable results as Dr. Greenhow appears to be; nevertheless, I recommend it as a means which ought not to be lost sight of by those who have frequent opportunities of witnessing these accidents, and one which will succeed in eight cases out of ten. Should the preceding remarks meet your approbation, an insertion in your excellent journal would be deemed a favour by, sir,

Your obedient servant,
JESSE LEACH, M.R.C.S. &c.

Heywood, Oct. 21, 1838.

DEATH OF A CHILD FROM FRIGHT OF THE MOTHER.

To the Editor of the Medical Gazette.

SIR,

IF you think the inclosed worthy a place in your journal, you can insert it,

570.—XXIII.

and believe me, with much respect, a subscriber, and your's truly,

B. RIDGE, M.R.C.S.L.

Terrace, Putney, Oct. 16, 1838.

M. H., æt. 37, a laundress of industrious and cleanly habits, and of exceedingly anxious temperament, has had five children, and lost the use of the right mamma, from the nipple sloughing off, when suckling her third child. Was confined with her fifth child, a boy, on the 30th July, 1838, and both mother and child did well. At the end of the fifth week she went with her husband to Deptford, and whilst on the road, the axle-tree of the omnibus they were in broke, which gave her a sudden fright, and some friends who were with her remarked how very pale she became, and continued to be the whole day. She, however, got home safely, and apparently no inconvenience ensued: the child seemed to do as well as before, though the mother noticed how very quiet it was, as did also the women who were accustomed to come to her house to wash; it did not cry as usual during the time of dressing and washing, but became listless, and free from those smiles incidental to children of that age; neither did it seem to require the breast so frequently as before; however, as long as it continued well, nothing was thought of these changes; when on the ninth day after the accident the child had a convulsion, from which it was a long time recovering, and in consequence of that I was sent for. I found it much depressed, listless, and not crying or fractious, as children are when unwell; having frequent curdled stools, sometimes mixed with green, at the same time presenting no other symptom but that of slight disorder in the bowels; the pulse was low and frequent. The chalk mixture with a little camphor julep was administered, and the child the next day appeared better, but the bowels not having been opened, a small powder of hydr. c. creta and rhubarb was given it, and two hours after a tea-spoonful of castor oil; this brought away a large curdled green stool, plentifully mixed with slime. The chalk mixture, &c. administered again; and after this, as the bowels seemed comfortable, no other aperient was given.

On the third day, I remarked to the mother that the child appeared to me to

be starved, and ordered in consequence a gentle stimulating tonic, and the mother to take three or four glasses of port-wine a day, with more nourishing diet. (But I should here state, that the circumstance of her fright was not mentioned to me till after the child's decease.)

The mother said the child had sucked, but only at short intervals, and that she also fed it. I noticed it at the breast: it took a few sucks, and then left off; and then a few more, and so on. At the same time I requested the mother to save me some of her milk, which was done; and my suspicions were verified, for certainly it was very poor: no cream or substance of any kind floating on the surface, but more like the thin milk-and-water-looking secretion that sometimes oozes from the mamme during utero-gestation. In consequence she was ordered more nourishing things, and an increase of wine. Notwithstanding this, nothing seemed to make an impression on the child, and it died on the fifth day of my attendance, and the fourteenth from the mother's fright.

As I could not account for the child's death, I requested a post-mortem examination, which was readily granted me; and whilst talking concerning the illness and death of her child, the mother said, "Do you think, sir, my fright could have had any thing to do with it?" when she related the circumstance, and which shewed that that alone was the cause,—the child receiving an imperfect nourishment from the mother, its daily allowance gradually reduced, and its own little powers called on to bear against the shock, till they became exhausted.

It no doubt died in consequence of the fright affecting the milk of the mother, and being gradually starved to death; whilst no one was to blame. Medical aid was had directly the first symptom of illness occurred, the apparent cause soon discovered, the child was then sustained by tonics, and the mother by wine and other nourishing things; but the shock had been too great.

The *post-mortem* examination confirmed the fact. The whole alimentary canal was contracted for want of food; very little blood in the large vessels and heart; a small quantity of bile in the gall-bladder; the liver rather pale, but healthy, as likewise all the viscera. The large vessels contained a small por-

tion of yellow feces, mixed with a few curds; the cæcum a very small portion, but a large secretion of mucus from its lining membrane ready for use. The process *vermiformis*, when slit up, presented the same appearance; on which I beg to offer a remark before I close this paper, which struck me at the time. The size and fulness of this process—the unusual quantity of mucus on its lining membrane—the immediate communication with the cæcum;—what can this process be for? Can it be to supply the cæcum with any quantity of mucus, large or small, for the purposes of nature (as that organ is such a reservoir for all digested materials and feculent matter) after birth, or for assisting in moistening and keeping it in a healthy state during the foetal life? I certainly have never been able to discover any glandular appearance in it; but still it might be of service to the cæcum, by contributing mucus to the feculent matters passing through it. The cæcum must very soon after the birth be called into action, and contract very forcibly, to expel the meconium which pours down from the small intestines, and more particularly as some men are so fond of giving castor oil the moment a child is born. However, till a discovery is made of its real use, any opinion, however hazarded, is pardonable, as no one can say directly, "It is not so."

NEGLECT OF MEDICAL EVIDENCE BY CORONERS.

To the Editor of the Medical Gazette.

SIR,

On the 17th of this month, about six in the evening, I was called to the Cloth Workers' Almshouses in Islington, to attend a woman named Ann Sharp, aged 50, who was stated to be in a dangerous state.

On my arrival I found her lying on her back on a sofa, quite insensible, with a full pulse, the skin warm, breathing laborious, but not so stertorous as is generally found in cases of apoplexy. The woman was described to have been previously very healthy. She had a slender neck and fair skin. I was informed that she had been first attacked at ten A.M. of the same day, having lain

for eight hours without any medical attendance. I immediately bled her to sixteen ounces, ordered her head to be shaved, and vinegar and water applied to the scalp. At nine o'clock, three hours after I saw her, she died. I directed the body not to be disturbed till the coroner's jury had seen it, and kept myself in readiness to make a post-mortem examination. At considerable personal inconvenience I staid at home during the day on which the inquest sat, expecting to be summoned. To my astonishment, and to that of others who heard of the case, no medical evidence was thought necessary.

Now, sir, if inquests are thus managed, the institution of a coroner's court is something like an expensive farce, and the sooner the county is saved the expense of the establishment the better. I give Mr. Wakley every credit for his exertions in procuring the act regarding the medical evidence on coroners' inquests; but unless a compulsory clause is added, respecting medical men, the law is almost a dead letter. I may observe, however, that in all cases of inquests at the Infirmary here, to which I am surgeon, I am uniformly called to give evidence. This is not to be wondered at, considering that no fee is given to the medical officers of public institutions.—I remain, sir,

Your obedient servant,
ROBERT SEMPLE,
Surgeon.

Oct. 24, 1838.

[The abuse detailed in this letter is exactly in keeping with information we have received from various parts of the country. The change made, we believe, during the last session of parliament in the mode of payment, has had the effect of deterring coroners from calling medical witnesses. Many, we are informed, who on the first passing of Mr. Wakley's bill used to avail themselves of professional evidence, now decline to do so.—ED. GAZ.]

SINGULAR EFFECTS OF PRINTING IN GOLD.

To the Editor of the Medical Gazette.

SIR,

SHOULD the accompanying case appear worthy of being recorded, I would beg as a favour its insertion in the Medical

Gazette, not being aware that any person as yet has noticed this affection, which may perhaps be as novel as its cause, viz. the printing of "Golden Sun" newspapers!

July 17th, John Oakey, æt. 19, a lad of pale, scrofulous complexion, applied at this institution for relief of a most distressing itching of the scrotum, and was admitted under the care of Mr. Caswall, whom I have to thank for his kindness in permitting me to supply the notes of this case.

On examining the part, it seemed relaxed and inflamed, the sebaceous follicles considerably enlarged, and round the roots of the hairs were small scabs, caused by his scratching the part, to relieve the tingling sensation. The hair on the scrotum and pubes was of a decided grass-green colour, and though the irritation resembled that produced by the pediculus pubis, I could discover none of these vermin or their ova.

On inquiry, the lad referred these symptoms to his occupation at a newspaper office, being engaged in printing the Golden Sun paper—so named from its golden type. It appears this hue is communicated by brushing a fine bronze-coloured powder (composed, according to the workmen's account, of copperas, verdigris, and quicksilver) over the type, which is first printed in yellow ink. This powder is given to those employed in ounce packets, and about forty hands were thus employed, almost all of whom had been forced after a time to give up this work, some keeping at it only two days; others for a week or more; but all suffering more or less from its effects.

The hair on his head and in the axilla was of the same colour, and he complained of itching in these parts, and about the wrists, though in a less degree, and the hair felt peculiarly harsh, dry, and matted.

He stated that on the third day of being thus employed, he had been seized with vomiting of a green-coloured fluid, and a sensation of heat and constriction in the œsophagus, with pain in the stomach, which he referred to swallowing and inhaling portions of the powder diffused through the air of the room: this was followed by epistaxis, recurring at intervals, itching of the before-mentioned parts, more especially of the pubes and scrotum, tenderness of the epigastrium and bowels, accompanied by loss of appetite and

rest. As his bowels were confined, and his stomach irritable, he was ordered,

Pulv. Jalapæ cum Hydrarg. Chlorid. xij.
stat. sum. Mist. Effervesc. ʒiiss.; c.
Mag. Sulph. ʒj. ter indies.

and to relieve the itching, fotsu papaveris, with occasional poultices.

His continual scratching (being unable to keep his hand out of his flap for five minutes at a time) had destroyed the character of the eruption so much, as to put it out of my power to state positively what it originally was, but it seemed to have been primarily papular, subsequently assuming a vesicular appearance.

19th.—The eruption has decreased, and the irritation is much relieved, but the hair still retains its green hue; the tenderness of the epigastrium and sickness have left him, his tongue is clean, and he sleeps well at night.

Rep. Pulv. et Mist.

26th.—He returned quite well, but still with the hair on his pubes, scrotum, and head quite green, though gradually fading away. Ordered to continue his medicine, and return in a week, using in the meantime common pomatum to the hair, to soften it and remove its harsh wiry character.

Unfortunately, like too many dispensary patients, being relieved, he never returned to give up his letter, or obtain a letter of thanks to the party who had recommended him, and thus he deprived me of the opportunity of observing how his hair resumed its natural hue (a sandy colour, it seemed to be), as also of giving the termination of his case.

This case having excited my curiosity, I asked and obtained permission to see the process of printing these papers. They are printed with a yellow ink, composed of size and gamboge, and then handed over to men who, with a common hat-brush, distribute the powder over the paper, which adheres to the moist printed portions. About a dozen persons were thus engaged when I visited the office, all of whom complained more or less of the same symptoms. Some added, that this irritating powder had caused deep ulcers on the genitals; others declared it had salivated them to a certain extent; but though their gums appeared slightly spongy, they hardly seemed more so than those of most persons whose

stomachs are out of order; and I could not detect any mercurial factor.

I wished much to be allowed to have a portion of this powder for chemical examination, but my request could not be granted, as its composition is kept a secret. I was told it was prepared in Germany; it looked like very fine brass filings; the whole air of the room was loaded with it, and my coat glistened, as also did my face and hair, which rivalled in brightness the wig of Caligula, who had recourse to gold-dust to produce the effect I obtained so cheaply.

This case would have been forwarded to you long before this, but unfortunately I had mislaid the notes, and have only now found them. I have referred in vain to the works of Thackrah, Ramazzini, and Patissier, as also to the Dictionnaire des Arts—none mention this mode of gilding, or any similar effects on gilders. Believing it, therefore, to be as new, as this new process of “illuminating” newspapers, I have done myself the pleasure of sending you this very imperfect notice of it, and remain, sir,—Yours, &c. &c.

GURNEY TURNER,

General Dispensary, M.R.C.S., &c.
Oct. 24, 1838.

P.S.—The illuminated letters in *Misals* were executed, I believe, either in gold ink, prepared by grinding gold leaf with size, or by laying gold leaf in the letter drawn in size, and then removing the superfluous portions. I fancy I remember having seen a work printed in gold letters, containing an account of the coronation of George IV., but do not know how the effect was produced.

MEDICAL GAZETTE.

Saturday, November 3, 1838.

“*Licet omnibus, licet etiam nihil, dignitatem Artis Medice tue: potestas modo veniendi in publicam sit, dicendi periculum non recuso.*”
CICERO.

LONDON UNIVERSITY DEGREES.

ACCORDING to promise we now proceed to comment on the scheme which we published last week from the Report of the Medical Faculty of the London Uni-

versity. Let us first consider the examination which they require a student to have passed, before he can enter into the territory at whose opposite and far distant boundary he may perhaps obtain the object of his ambition—the degree of Doctor of Medicine.

Now there are two principal purposes to which such a preliminary examination may be made subservient: in the one, as a test of respectability; in the other, as a test of intellect. In the former view, such examinations are employed to prevent any one from entering into a society till he has proved himself honourably entitled to associate with its members. In the world at large he is introduced by some members of the society he desires to move in, and the rest, relying on the axiom, “*noscitur à sociis*,” admit him, and entertain him, as long as his conduct is in accordance with their rules. But in professions it is a different matter; the advantages of admission are more tangible and direct; and the delinquencies of an individual member are often less injurious to himself than to the profession at large. Hence it has been found necessary to establish more stringent laws in regard to the admission of new members, even to the right of studying it, with the view of practising; and an additional test of their previous respectability has been required. That which has seemed most advantageous is the test of education, because it affords at the same time evidence, to a certain extent, of a man's pecuniary means, of the respectability of his family, and of his intellectual attainments. Preliminary examinations have generally been based on the knowledge which the student can shew himself to be possessed of in classical literature; and his ability to pass has served to show that he has been educated at a school, to which the sons of those who move in what are called

the better ranks of society were in the habit of resorting; and on the whole, this plan has been found sufficient for the purpose.

This is a long preamble, and on a subject which most assuredly we never imagined would be found illustrated in the democratic University of London. The principles upon which that University set out, and upon which it ought, in consistency, to have been conducted, were, that nothing but intellectual fitness for the grade he sought to move in should be demanded of the candidate; that the test of intellect alone should be applied to decide whether any man, be his other qualifications what they might, should be admitted to academic privileges. What! it was urged, is it to be borne that, in the nineteenth century, the march of intellect should be impeded by collegiate monopolies? Shall the poor man have his poverty aggrieved by exclusion from the intellectual advantages for which he is as well fitted and as deserving as his fortuitously richer neighbour? Shall a secondary thing, like religion, (we speak the language of others) still exclude all but those who belong to the more powerful sect from the honours and rewards of talent? Shall the “fetters of the seventeenth century” be still fastened upon us—the freemen of the nineteenth?

Amidst much error and exaggeration, there was something fair in the demand that neither religious nor pecuniary differences should be the cause of a man's exclusion from the opportunities of cultivating his intellect, and of reaping the rewards of his industry and talent in the higher grades of the secular professions. Well, a University is established; those who had demanded it are vested with plenary power, and they sit beneath the auspices of a powerful and favouring government. One would have

thought that nothing else was necessary now than to throw open at once the portals of learning and of honour, and to proclaim, in a word, that the barriers which riches and religion had set up against the progress of the mind were thrown down for ever. But no—the Council of the liberal University must afford another proof that the worst aristocracy is a democracy in power. They meet, and gravely deliberate; they grow more aristocratic every day; they begin to assume the styles and titles which, when borne by others, they had so despised; and after much agitation, and many changes of their schemes, each that is proposed being more exclusive than the last, they pompously announce a plan fully as exclusive as that of any University in the kingdom. They admit, indeed, men of any or of no religion; but though they need not be Christians, they must be gentlemen; they must be “the sons of persons moving in a higher class of society,” for “we wish to keep up the estimation which physicians in this country have always maintained*.”

All this would have been very well, if an aristocratic University had been needed; but while Cambridge and Oxford exist, the small number of the sons of the higher classes who will have any scruple against resorting to them will be far too small to maintain another University of the same kind. An University in London, of which, as we have often said, we have always supported the establishment, should have been one which would not only have satisfied the demands and deserts of those who conscientiously dissent from the doctrines of the Church of England, but which should have conferred on those who, from limited means or other circumstances, are prevented from graduating at Cambridge or Oxford, advantages similar to

those which the old Universities afford. Dissenters alone can never maintain an expensive University, and the London University will never be able to offer advantages sufficient to attract the sons of the richer churchmen. Its endeavour should have been to establish an aristocracy of professional intellect: with a comparative disregard of the literary education of its graduates, it should have instituted a course of practical education, and of practical examinations, which should have ensured that these who possessed its diplomas were fully competent to the highest duties of their profession. It would have gained far more both of honour and of profit by having educated a large class of sound practitioners, than by an abortive rivalry with Oxford and Cambridge.

But it is truly unfortunate that when they had determined to have a very aristocratic scheme, the Medical Faculty should have set about it so awkwardly as they have done. The intention appears to have been to make the preliminary examination a test of respectability under the guise of a test of intellect alone; and it is therefore loaded with subjects of the most heterogeneous and most irrelevant character; candidates are to be learned “*omnibus rebus, cum quibusdam aliis.*” To find out how far a candidate’s education has been expensive, and thereby how rich his parents are, it is amply sufficient to take a single subject of a certain difficulty. Thus, the translation of the Greek of Hippocrates and Aretæus into Latin, as required by the College of Physicians, can leave little doubt that the competent candidate has been educated at a school of respectability. But the Medical Faculty thought such a system to be too openly a test of mere respectability for their use, who wished at least to seem careless of that qualification, and to regard it as of minor importance to intellectual acquirements.

* Letter from C. L., one of the better class of the Council, in our number for August 11th.

In the vast selection of subjects which they have made, they have been singularly infelicitous, and one might almost imagine that they had by design included every art and science but those which minister to the art and science of practical medicine. There are classics of all kinds but the medical—Homer, Xenophon, Virgil, Horace, Sallust, Cæsar, Livy, Cicero. There are French, or German, and English (as if the man who could translate Homer and Horace could neither read nor write his mother tongue). Then there is the History of Greece to the death of Alexander, a period which exactly excludes the earliest part of the history of medicine, after Hippocrates, in the Alexandrian school; the history of Rome to the death of Augustus—that is, to the commencement of the history of medicine in Rome; and the history of England to the end of the 17th century, so as just to come upon the verge of the history of medicine in this country; as if in each case care had been taken to leave off where the history of a country began to be of interest in its relation to the progress of the medical profession. Then we have arithmetic up to compound interest; algebra to quadratic equations—logarithms, mensuration, and the first book of Euclid! There are mechanics and hydrostatics, hydraulics and pneumatics—acoustics—heat, electricity and magnetism—optics and astronomy!! (We marvel much that astrology is not in the number, if only for its relation to animal magnetism). Ultimately they require the elements of logic and of moral philosophy.

Was ever such a list set before any man? Why—the candidate who can “show a competent knowledge of all these subjects*,” ought to be received with open arms, and straightway elected a member of the medical faculty; for surely none of its present

members could pretend to accomplish such a feat as this.

Scarcely one pupil educated at Eton, Charter-house, Shrewsbury, &c. will be unable to pass this examination without special preparation, if it be conducted with the severity which the Council threaten, and which we believe they mean to carry into effect; for such men as the Rev. Connop Thirlwall and the Rev. Robert Murphy, whom we find they have lately appointed examiners, are not of the class who will be contented with a superficial or popular knowledge of their subjects. The examination is about equivalent in quality, and far more than equal in quantity, to that which has to be passed for a common degree in arts at either Cambridge or Oxford, after the education of the candidate at either of those Universities for three or four years. So that as it appears that they expect students to begin their medical studies before they are nineteen; that is, as soon as possible after they leave school, the candidates for their degrees must be equal at the outset to the majority of Bachelors of Arts of Cambridge and Oxford. There is much of vanity in all this—they imagine that the great public schools will alter, extend, and accelerate their modes of teaching, to adapt their pupils for passing an examination in the London University—that they will convert the present solid system of education at these establishments into a popular superficiality. But the Council will be grievously disappointed—old institutions are not so easily moved—they will continue, we are convinced, in spite of any number of new Universities, rather to teach a few things well than a number ill.

If, then, the Council adopt the strict method of examination, which their style and expressions threaten, the examiners will hold sinecures. But we say “if,” because it is just possible

* Report, p. 170.

that the examination may be made to adapt itself exactly to a peculiar though small class of young men, to whom the medical faculty of the University cannot but be favourable;—we mean the pupils of the Gower Street College. The teachers in Gower Street will, of course, adopt at once any plan which may give them the slightest appearance of connexion with the University, or of advantage over the other public schools, and will teach any number of subjects to the least necessary depth, provided they can then have a monopoly of those who intend to take medical degrees in London. We also see too much reason to suspect that it is a leading point in the legislation for this University to make it a means of assisting various individuals who are connected with this its favourite college.

It would appear that in their pride of exaltation to be legislators, they imagine that they shall attract those who have graduated elsewhere to come and crown their academic honours with a degree at Somerset House. Indeed, this is almost implied in the opening sentence of the Report*. “Candidates for Degrees in Medicine shall be required to have taken a degree in Arts in this University, or in a University, the degrees granted by which are recognised by the Senate of this University.” Indeed! We can scarcely imagine the anxiety with which the Senates of Cambridge and Oxford will wait to hear whether they are to be among the favoured number of the recognised.

Whatever be the intended severity of examination, this at least is certain, that the omission of nearly every thing relating to medicine from the preliminary education required is most happily adapted to exclude all those for whom the projectors originally professed so much esteem; all that large class who now

go to Apothecaries’ Hall,—that is, the whole general class of medical students. There are many who, after having been educated at schools of but moderate respectability, spend many years in the pursuit of medical knowledge, to the comparative and very praiseworthy neglect of irrelevant subjects, who desire to be physicians, and are obliged to take degrees which confer no honour, because regulations of other Universities prevent them, without great trouble and expense, from obtaining those which do. This is the class to which the London University should have catered; it should have drawn from the more talented of the medical students—it should have conferred its honours upon them, and it would then have received an abundant return of honours from the reputation which they in their turn would have gained for it. But it is evident that “medical students” are not respectable enough for the University of London.

In an early number we shall return to this subject; for if this same precious code be once adopted, discussion will come too late: at present we shall only add our conviction that the proposed regulations evidently emanate from a set of speculatists not practically acquainted with medical education, *and cannot be carried into effect.*

EXAMINATION FOR B.A. AT CAMBRIDGE.

THE following list of the subjects of examination for the degree of B.A. at Cambridge, will be interesting when compared with that published last week for the same degree in the London University, and includes all the subjects which will be required in the more severe system of examination which will come into force in January 1841:—

The Acts of the Apostles, one of the Greek and one of the Latin Classics.

Paley’s Moral Philosophy.

Euclid.—Books i. ii. iii. and part of vi. Arithmetic.

Algebra.—The simpler parts up to equations.

Mechanics.—The parts which can be done by the help of the simpler parts of mathematics, such as the composition and resolution of forces, the mechanical powers, centre of gravity, &c.

Hydrostatics.—The simpler parts, such as the pressure of non-elastic fluids—specific gravities.

The candidate must shew a competent knowledge of all these subjects.

It will be seen, that while the London University requires the same, or rather a greater amount of each of these subjects, it demands, besides, an equivalent, on Grecian, Roman, and English history—of the French or German language—and of the principles of acoustics, heat, electricity, magnetism, optics, astronomy, and logic !!!

It is unnecessary, also, to add, that candidates for medical degrees at Cambridge are not required to pass even the above examination, but may proceed at once to their B.M. degree without taking that of B.A. The only essential literary examination which they have to undergo, is that which is commonly called the Little-go, and which includes

One of the Gospels in Greek,
Paley's Evidences,
A Greek subject and
A Latin subject.

GLASGOW EYE INFIRMARY.

CLINICAL LECTURES BY DR. WOOD,
ASSISTANT-SURGEON.

Origin of Glasgow Eye Infirmary—Ophthalmia of New-born Infants—History—Treatment—Cases.

It will be not an unfitting commencement of the lectures, the duty of delivering which has been assigned to me, to give you a short sketch of the origin and history of this Infirmary. There may occur to some among you, in future life, opportunities of establishing medical charities, by which, while the poor are relieved, your own knowledge will be, and perhaps your reputation may be, increased. Information bearing upon this topic, therefore is not out of place.

The Glasgow Eye Infirmary was instituted fourteen years ago, and is indebted for its origin to the united exertions of the late Dr. Monteth, and Dr. Mackenzie, the present senior surgeon.

The fiscal affairs of the institution are managed by a president, a treasurer, a secretary, and twelve directors appointed by the subscribers. Four directors retire annually, and their places are supplied by a vote of an annual meeting of those who contribute to the funds of the infirmary. Twelve gentlemen are appointed in addition, all of whom are requested in rotation to visit the infirmary, and record an opinion as to its efficiency and management; and to mediate in any disputes between the servants and patients. These gentlemen are understood to subscribe to the funds of the infirmary: the extent and derivation of which I shall mention. Our income varies very little lately. We receive about 330*l.* a year, entirely from charitable donations and legacies. All who contribute to our funds are permitted an unlimited power of recommendation. Indeed it is very rare that any one is turned away from our doors, recommended or not, unless evidently a person assuming the garb of poverty to avoid the payment of a just fee.

There have been admitted during these fourteen years nearly 9,000 patients. At present our daily attendance may average forty, and we admit daily about three new cases. In the house ten patients can be accommodated, and this accommodation can easily be increased. Patients requiring operations are preferred for admission. This is not a cheap institution. We look to nothing so much as to the cure of the patients; and, including out and in-patients, the average cost of each has hitherto been 6*s.* 1½*d.* dearer than in some dispensaries. The medical attendants have no emolument. A minute record of every case is kept, as you know, and is open for your inspection. The subscribers are usually 350.

The medical department is conducted by two surgeons, and an assistant surgeon. The two surgeons act alternately for three months at a time. The duty of the assistant-surgeon, which office I hold, is to act in the absence of the principal surgeon, and for the present it has been arranged that, while I continue these lectures, I shall admit and take exclusive care of a certain number of patients, so that I shall be enabled to make my lectures more purely clinical than this can assume to be.

Until this arrangement can be carried into effect, I mean to direct your attention to the history of some diseases of the eye, which I deem interesting to the student;

and cases of which we have the means of submitting to your observation.

I shall begin by drawing your attention to the ophthalmia of new-born children—*ophthalmia neonatorum*. When you commence practice there is every probability that many of your earlier cases will be among the poor, and women in childbed will form a considerable number of your patients. I can hardly imagine a more mortifying feeling to a young practitioner than that which would be felt by him, were he to neglect a case of *ophthalmia neonatorum*. By saying the case was quite common, and of little importance, he may allay the fears of the parents for the time, but if at the end of a week the eyes of the child are found to be destroyed, could he answer to his conscience as entrusted with the health of his fellow-creatures? It is not a very rare occurrence in the practice of those who are attached to the study of eye diseases, to find infants whose eyes have been totally ruined by inattention or ignorance. I press the subject on your consideration, then; first, because no inflammatory disease of the eye is, in this country, so frequent a cause of blindness. Second, because no inflammation of the eye is more fatal when neglected. Third, because when taken in time, it is a disease more under medical control, probably, than any of its class.

Symptoms.—Increased vascularity of the conjunctiva, particularly the palpebral conjunctiva. It is at this stage that the practitioner may err by not inspecting the eyes of his infant patients. The increased vascularity is soon followed by a discharge of puriform matter, and the disease can no longer be mistaken. Its course you may learn from the cases before you. Unfortunately we have too many opportunities of observing its fatal termination here; for the mothers, having no one to send with their infants, and being unable to leave their houses before a fortnight or three weeks after their delivery, delay making application until it is too late to save the cornea.

Prognosis.—If the corneæ are clear on admission, we find hardly an instance where the eyes are not saved. In such cases, then, the prognosis is favourable, if the attendance of the patient be regular.

If the cornea is hazy or superficially ulcerated, we may anticipate an opacity of one kind or other, of which we should warn the parents, but which may be diminished or even removed by treatment. In those unfortunate cases in which the corneæ have burst, and the irides protruded, we can at the time promise nothing more than to alleviate the pain. The sequelæ of *ophthalmia neonatorum* I mean

to direct your attention to on a future occasion.

Causes.—With regard to the causes of this disease, I shall give you quotations from several high authorities; but before doing so, I may state that any observations I have had it in my power to make have led me to the following conclusion. Leucorrhœa in the mother is the most frequent cause of ophthalmia in new-born infants. It requires some tact to investigate this, and you will in vain expect a confession of gonorrhœa from the mother of an infant in this country. Yet I have no doubt that some of our worst cases have been gonorrhœal. Exposure to a bright light, or to cold, and washing the child's head with spirits, rancid soap, &c. are unsafe. The disease excited by the latter causes, however, do not seem to me to be so dangerous as those which we attribute to a vaginal discharge. We might divide the disease, then, thus:—1. Gonorrhœal ophthalmia neonatorum—not frequent but very dangerous; 2, leucorrhœal—common, dangerous; 3, catarrhal, arising from improper exposure—generally mild, and easily managed; 4, traumatic, from carelessness of the nurse in treating the infant. The cause of this ophthalmia should be carefully investigated, and its progress watched by the surgeon.

We now come to the authorities. Dr. Mackenzie says (p. 432 of his *Treatise on the Eye*), “We have reason to believe that this disease is, in general, an inoculation of the conjunctiva by leucorrhœal fluid.” He admits that cold exposure to the light, &c., may cause this disease. No doubt of it: and I again beg of you, as likely soon to have it in your power, to investigate the causes of this disease. We have not *one* ophthalmia neonatorum; we have several, differing in their causes, their symptoms, and their treatment. Mr. Lawrence (p. 169, of *Treatise on Diseases of the Eye*, edition 1833) states, that “in a great proportion of cases there is vaginal discharge from the mother, leucorrhœa, and sometimes gonorrhœa.” Again, he says, “Purulent ophthalmia is often seen in the children of healthy mothers, at least of such as appear perfectly healthy, and deny, when questioned, the existence of vaginal discharge in any shape. All the influences which depress the system are favourable to the appearance of purulent ophthalmia.”

Having heard the opinions of two of our ablest authorities at home, I now quote that of M. Sanson, of the *Hôtel Dieu*, in Paris, as given in the *Dictionnaire de Médecine et de Chirurgie Pratiques*, (vol. 12.) He seems to agree altogether with Lawrence, and Lawrence and Mackenzie do not essentially differ on this subject. Besides leucorrhœal and gonorrhœal infec-

tion, M. Sanson thinks that defective nutriment, cold, damp, want of proper maternal care, &c. are causes of this disease. I need hardly repeat, that any disease so originating would be catarrhal or traumatic.

From Paris we return to Dublin, and we find that Dr. Jacob (*Cyclopædia of Practical Medicine*, vol. 3, article *Ophthalmia*) gives his opinion in this sense—"The investigation of the *causes* of purulent ophthalmia in infants is not attended with much difficulty." I must say that I differ from Dr. Jacob here. In Glasgow, at least, we often find a great difficulty in ascertaining the cause of this; aye, and of many other diseases. The Scotch are said to be peculiarly seerctive. Dr. Jacob's treatise is well deserving of your attention.

In a discussion which took place at a meeting of the medical section of the British Association, in 1835, in Dublin, and which I quote from the *Dublin Journal*, vol. 8, Dr. Evory Kennedy said, that "a great deal of difficulty attended the investigation of the origin of purulent ophthalmia, as connected with a specific virus. As far as his experience went, the proportion of cases which could be distinctly referred to gonorrhœa, or to the leucorrhœal discharge, was very small." My opinion is quite different, or rather I ought to say, more correctly, that my experience is different from that of the eminent physician I have just mentioned. You will find, too, that Dr. Jacob and Dr. Kennedy are not of the same opinion as to the difficulty of discovering the *cause* of ophthalmia neonatorum. At the discussion to which I am alluding, Dr. Beatty agreed as to the cause with Dr. Kennedy, not having in many cases observed vaginal discharge in the mother. On the other hand, Mr. Byrne is represented to have said, "that in every case which had fallen under his care he could trace the disease to infection." Dr. F. H. Ramsbotham (see his lecture in the *MEDICAL GAZETTE*, vol. 16) does not suppose this disease to depend in general upon a specific virus. The latest work I have seen on the subject is by Dr. Slade. He admits the leucorrhœal origin of the disease; but it is not in my power at present to enter into any detail of his opinions.

Treatment.—I shall not long detain you upon this subject. You see our daily practice; and our books are quite at your service for inspection. When the conjunctiva is swollen, scarification of the internal surface of the lids is a powerful remedy. Leeching the eyelid is generally recommended, and is, no doubt, very efficient. It is not, however, so much under the command of the practitioner in an infirmary, and as apt to be mismanaged

by lazy attendants and careless mothers. For this reason I prefer scarification. A drop of the solution of nitrate of silver (10 grains to the ounce of water) is put into the eye daily, or is alternated, particularly if the case be chronic or tedious, with Mr. Guthrie's ointment of nitrate of silver. Blistering behind the ears is occasionally, but not very often necessary. Perhaps the most important part of the local treatment is, an assiduous attention to complete cleanliness. For this purpose we use a solution of one grain of corrosive sublimate in eight ounces of water, and the eye carefully cleansed with it four or six times a day, or, indeed, as often as the puriform discharge has accumulated—an accumulation which is a frequent cause of great mischief. Attention to the general health must not be neglected; and if the alvine discharges are unnatural, small doses of calomel, or of calomel and rhubarb, will be found useful.

CASE I.—J. S., æt. eight days; ophthalmia neonatorum commenced three days after birth; discharge very copious; worse in left eye.

A leech to left upper lid. Ung. Præc. Rubr.; Gutta Sol. Nitr. Arg. gr. x.; Calomelanos, gr. j. o. n.

Next day the leech was repeated. On the week following the ointment was used instead of the drops of nitrate of silver, and the child continuing to improve, was dismissed shortly afterwards. This case affords an example of those which, being taken early, and properly treated, are not followed by any bad results. It is No. 8650. The leeches were of decided benefit.

CASE II.—Bad consequences of neglect. I quote from the journals of a former year. M. B., æt. eight days; ophthalmia neonatorum of eight days' standing, affecting both eyes. Cornea safe. Leeches to the temples, and blisters behind the ears. The patient was admitted on the 22nd of October. On the 1st of November it is reported, that owing to the illness of the mother the child has not been brought to the infirmary since the day of admission. The discharge is profuse, but the corneæ are still apparently safe. Scarification of the inner surface of lids. Nitrate of silver drops, and the usual lotion and ointment, were ordered. On the third day an ulcer was observed on the cornea of right eye. The discharge less. Belladonna. On the 8th a blister applied behind each ear, and the scarification repeated. On the 12th reported as improved. On the 24th of the following month leucoma in the seat of the ulcer in right cornea, the only symptom remaining. Had the child been brought regularly at first to the infirmary

it is not likely that either ulcer or leucoma would have occurred.

CASE III.—Another case neglected. J. C., æt. four months; both corneæ prominent and conical, the irides adhering to the posterior surfaces, leaving the pupils distinctly visible, though the left cornea is whitish. The results of purulent ophthalmia hitherto unattended. This patient is still under treatment; the vision very imperfect, although slowly improving. Much might have been done for this child at an early stage of its disease.

CASE IV.—Danger of delay. J. M., æt. five weeks; affected soon after birth. Left cornea has given way. The right eye was inflamed, but the cornea entire. By active treatment, on the usual principles, the right eye was saved, but the vision of the left was irretrievably lost.

CASE V.—In attendance. No. 8852, aged four weeks; ophthalmia of both eyes. Disease noticed six days after birth; discharge great; cornea clear.

Scarification; Nitras Argenti, in solution. Ung. Pr. Rubri; Collyrium; latterly a leech to each upper lid.

You can observe for yourselves the progress of the case. I may mention, that the mother had a vaginal discharge, probably leucorrhœa, at the time of the child's birth.

KING'S COLLEGE MEDICAL AND SCIENTIFIC SOCIETY.

October 25, 1838.

THIS body, which has existed several years, held its first meeting for the present session on Thursday evening; Professor ARNOTT in the chair.

The introductory address, read by Mr. Bowman, the secretary, was devoted to a critical examination of the advantages offered by debating societies to the medical student in the more advanced stages of his education. The principal objections that have been made to them were investigated in the course of it, and those circumstances adverted to particularly which might tend to diminish their value. Many of the remarks bore especial reference to the society assembled, at the meeting of which, punctual attendance, as well as a regular supply of papers, is required on the part of the members, and the chair is taken, in rotation, by the professors of the medical department of the college. It is, indeed, of the first consequence to the success and fair development of all academical associations of this description, that they be conducted with strict order and decorum—an end to be obtained, perhaps, in no more efficient manner than

by such regulations as have been just adverted to. When carried on with propriety, and in a candid and modest spirit, they open many avenues where the aspiring student may safely refresh himself from routine study, and in which all have an opportunity of reaping numerous benefits that are scarcely to be secured in any other way. But as this is not always at once admitted, it may not be out of place to mention some of those enumerated by Mr. Bowman.

The composition of an essay on some subjects connected with the profession of the writer must be granted to be a most useful mental exercise, leading him by strong incentives to store his mind with the facts and reasonings that relate to it—to compare, arrange, and weigh them—and perhaps even to strike out new paths of observation or inquiry for himself. What he thus acquires, too, will make a deeper impression than usual, and he may from this very period imbibe a fondness for his subject, which may be attended afterwards with results of real importance. It must be gratifying to the student to know that the germs of many useful, and of a few most excellent, contributions to the medical literature of our country have been traced by their authors to unpretending papers, read, while they were students, before debating societies; and though it be true that these results are but rarely to be looked for, there are others more generally met with, and which are not the less valuable because less immediately or distinctly recognised. Thus, the little business of composing papers has often, ere now, been instrumental in giving an impulse and a tone to the mind which has been felt beneficially throughout life. These facts entitle such societies at least to respect. The attention given to style and delivery, also, is obviously of much service, and need not be insisted on. Besides, the means thus afforded of making industry and talent known, though certainly less distinguished, are perhaps no less effectual incentives at the time than any system of academic honours, and this peculiar advantage attends them, not commonly possessed by the other, that, as merit is measured rather in an absolute than a comparative sense, there is small room left for corroding envy or disappointment to creep in, and mar every good result. At any rate, where professors or teachers undertake to preside in the arena, the production of these papers, by offering an honourable stimulus to industry, may be considered as an important help to the sessional prizes, now every where distributed; and with respect to their general bearing, it must be allowed they could be ill dispensed with, since by informing every

one of the extent of surface about to be trodden, by yielding a variety of topics for discussion, and by placing at least one person on his defence, they afford the best possible security for an orderly, expansive, and spirited debate.

The benefits to be derived from the second feature of such societies are perhaps sometimes incorrectly valued; since they seem not so much to consist in the fluency of speech, and power of addressing an audience with self-possession, which the debate affords an opportunity of cultivating, as in that readiness and precision of thought, which is in some measure a necessary consequence of engaging actively in the proceedings. Professional knowledge, also, is corrected and extended in a pleasing and often impressive way, and the debater is led to form a juster estimate of his own powers and acquirements, when he finds himself measured fairly in public by the side of others. These are advantages which could scarcely be so well attained by any other means. But do these societies tend to divert the mind from that regular application to a course of study which is so essential to success in academical pursuits? The question will be best answered by fact. In the debating societies of Edinburgh and Cambridge, very many of those men who have entered with most spirit into the business, and held the respective offices of the association during their studies, have since arrived at high eminence in almost every walk of life; and generally it has been found that those most zealous for the prosperity of such societies have been most successful, also, in honourable competition with their fellows. Indeed, when time, which should be otherwise appropriated, is unsuitably trifled away in this channel, it is much to be suspected that did this not present itself, some other, far worse, might be chosen.

Our space will not allow us to give any further abstract of Mr. Bowman's paper, though the importance of the subject to medical students might well warrant it. But from the zeal and interest displayed on the present occasion, there can be no doubt that the advantages offered by this and similar societies, in other schools, are becoming more generally appreciated.

PHYSICAL SOCIETY, GUY'S HOSPITAL.

20th October, 1833.

MR. BRANSBY COOPER IN THE CHAIR.

DR. HUGHES read the two following cases of

Aneurism of the Aorta.

CASE I.—A man, aged 40, when first seen by the relator, had suffered from cough for five years, and observed a pulsating tumor above the right sterno-clavicular articulation for six months. He presented the usual general and physical symptoms of aneurism of the arteria innominata, together with consolidation of the upper lobe of the right lung, and a feeble heart. In about a fortnight after, the tumor disappeared during the night, and could never after be discovered; the only apparent remains existing in the much larger size of the right than the left subclavian artery. At the same time, dyspnoea increased; the expectoration was more abundant, and was for two or three days slightly streaked with blood; and dysphagia now for the first time appeared. He began to sink rapidly, and the distress became excessive, till he expectorated about 3vj. of viscid reddish-brown purulent mucus. He was temporarily relieved; the sputa became again untinged with blood; and the general and physical symptoms were unchanged, with the exception of increased debility, till about four months after the disappearance of the tumor, when, after severe suffering for 36 hours, he expired. On examination, the upper lobe of the right lung was consolidated from old pneumonia, and contained in its centre an irregular cavity, capable of holding a pullet's egg, and a few scattered tubercles; the other parts of the lungs were comparatively free from disease, œdema and bronchitis alone affecting them. In front of the trachea was a small ulcerated opening, closed by a portion of fibrin communicating with an aneurism of the aorta. The heart was small and soft. The aorta ascendens was much dilated and diseased; the innominata much dilated and thickened. From its right side proceeded an aneurism as large as a chestnut; from its left in part, and partly from the arch of the aorta, proceeded another, as large as a hen's egg, pressing upon and having an ulcerated opening into the trachea. To the left of the left subclavian was a third aneurism, as large as a walnut. All contained firm, whitish fibrin. The right subclavian was much enlarged; the right carotid natural; the left carotid very small, and its mouth completely closed, a puckered depression alone marking its former situation; the mouth of the left subclavian also had been recently but entirely closed by the pressure of the aneurism near it.

In his observations, Dr. Hughes directed particular attention to the doubtful diagnosis, in consequence of the disappearance of the tumor, and the curious pathological fact of the occlusion of the left carotid

and subclavian arteries, and referred to a case operated on several years ago by Mr. Key, in which a similar obstruction of the left carotid was found after death.

CASE II.—A short stout man, aged 50, first came under the reciter's notice three years before his death, when he had a small pulsating tumor between the cartilages of the third and fourth ribs of the left side. From the medicines prescribed and the advice given, he did not suffer any even temporary inconvenience from it till September 1837, when he came into the hospital under Mr. Cooper, and when he suffered from the general symptoms of diseased heart. The tumor still existed, but had not increased in size; his complaints were not severe; he had no cough, ascites, œdema, hæmoptysis, or dysphagia; he suffered simply from a little dyspnoea, pain in the tumor and left shoulder. The physical signs were those of aneurism of the ascending aorta; and the heart itself appeared but little affected. After two months the tumor became rather suddenly reduced in size, and the pulsation communicated to it considerably decreased; the general symptoms at the same time were mitigated; but about a month afterwards he caught cold, and sank rather rapidly under an attack of bronchitis. On examination a large aneurism was found just above the sigmoid valves, passing to the left, and forming the tumor observed during life, and also behind the heart, and so compressing the right ventricle that it was rendered concave externally, and was upon the point of yielding to the pressure of the aneurism, its parietes being soft, red, and ulcerated. The valves of the pulmonary artery were curiously affected, one only being sound; another was reduced to one-third of its normal size by adhesion; and the third had almost entirely disappeared, in consequence of its union with the coats of the vessel. The pericardium was universally adherent, &c. &c.

The particular points adverted to by Dr. Hughes were—the cessation of all symptoms for three years, the rarity of the tumor presenting on the left of the sternum, the partial subsidence of the swelling, and the direction in which it had a tendency to burst.

Dr. Addison made some remarks on the symptoms and diagnosis of aneurism of the aorta. In aged individuals, constituting the large majority of these cases, the diagnosis was comparatively easy; but in young subjects, where usually there is little or no disease of the heart and adjacent vessels, the diagnosis was frequently reduced to a mere conjecture, and at all times most difficult. With regard to the

receding of an aneurismal tumor, after it had once made its appearance beyond the ribs or sternum, Dr. Addison said he very much doubted the fact. He had never been satisfied of the genuine occurrence of this circumstance; and he imagined that, in Dr. Hughes' illustrations, some tumor or enlarged vein might have been pushed forward by the artery behind, and this after a time subsiding, have given rise to the belief that it was a receding of the aneurism itself. The Doctor had seen several examples where an aneurismal tumor of the aorta had presented itself on the left of the sternum, and had found after death that, in these cases, the aneurism had arisen from that part of the vessel which is immediately above the sigmoid valves. When so situated, it was the Doctor's opinion that the aneurism invariably existed at that spot. There was now in Guy's a man in whom the aneurismal tumor protrudes at the left side of the sternum; and he had from this circumstance alone ventured to prognosticate its position accordingly.

Observations were also made by Dr. Guy, Mr. Greenwood, Mr. Hiff, the President; and by Dr. Hughes, in reply; after which the thanks of the Society were presented to Dr. Hughes for his interesting communication, and the meeting adjourned.

LONDON HOSPITAL.

CASES OF DOUBLE AMPUTATION.

To the Editor of the Medical Gazette.

SIR,

IN the last number of the British and Foreign Medical Review are two cases from an American journal, of double amputation of the legs, for mortification of the feet. It is surely a pity to be compelled to import, when our own hospitals, if properly used, would afford so many cases equally interesting. Perhaps the following brief notice, from memory, of three cases which occurred during the last winter in the London Hospital, may not be wholly uninteresting:—

Before mentioning them I would just allude to (a very trite subject, I fear) the loss which medical science sustains from the want of accurate and systematic records of the cases occurring in the metropolitan hospitals. For instance, if in the London Hospital (which, with one or two exceptions perhaps, admits more accidents than any hospital in the kingdom—certainly many more than any in London,) an accurate account were kept and published of

all accidents admitted, with treatment and results, and more detailed description of the more severe cases tabularly arranged, so as to be useful for statistical purposes, what a valuable addition would be made to our knowledge of the results of severe accidents in the metropolis. But if all the hospitals should do so, how invaluable a document would be produced. This will be thought, I dare say, a very chimerical suggestion. I can only say it *ought not* to be so; and if our love of science, and our freedom from mutual jealousies were greater, it *would not* be so.

There are two great classes of cases in which an inquiry conducted thus, would, I think, be very useful; I mean compound fractures, and severe contusions of the lower extremities. Increasing attention is given, and justly, to the endeavour to save the limb in cases of compound fracture; but it becomes a serious object of inquiry whether lives are not sometimes sacrificed in the attempt. It is often said, "If we do not succeed we can but take it off at last;" but this is a very fallacious hope: for, to say nothing of the physical powers, the moral powers of the patient are often so exhausted that he cannot summon up courage to undergo the operation, and in general feels little anxiety about life. This I have seen so frequently, that I feel very little dependence on such hopes, and I think it is a serious question, whether in bad cases amputation at once, with all its risks, would not shew a more favourable result.

Bad contusions of the lower extremities are very fatal accidents in the London hospitals, from erysipelatous and gangrenous inflammation; and it may be a question whether it would not be justifiable in very bad cases to substitute the smooth incision of amputation, for the contused and jammed extremity.

I do not think there would be much difficulty in getting details of the kind I have mentioned; and if the surgeons of the London or other hospitals were to offer their dressers a *small price for the most accurate report*, a double end would be answered.—I remain, sir,

Your obedient servant,

A PUPIL.

CASES.—1. This was a black sailor, æt. 30; he had been out of employ in the early part of the winter, and had got jobs at various wharfs, when he was much exposed; he was seized with the prevailing fever in the beginning of December, which terminated in gangrene of both feet, extending an inch or two above the ankles; the line of demarcation had clearly formed, and the process of separation considerably advanced. His health had much im-

proved, and his appetite was good. His legs were amputated by Mr. Luke, by the double flap operation: the left leg was first amputated, and the stump committed to the care of Mr. Curling to dress, and Mr. L. immediately proceeded to amputate the right leg. Both operations were completed in about four minutes, and the dressing occupied about fifteen*. He stood the operation well, roaring lustily. The stumps healed in greater part of their extent by adhesion, but considerable suppuration afterwards took place round the ends of the bones, and some exfoliation of the end of the left tibia. He recovered strength and substance rapidly, and having been a cook, proved quite a connoisseur in his eating and drinking. He left the hospital cured, in about eight weeks, a passage to his wife and family in the West Indies having been procured by the kind exertions of gentlemen connected with the hospital.

2. The second patient was a "parish boy," æt. about 17. The gangrene had in this case also been the result of fever, (the fever which was so very severe in White-chapel and the surrounding parishes during most part of the winter), which had made sad havoc in a delicate constitution. He was admitted almost reduced to a skeleton: pulse rapid; countenance anxious; tongue dry and cut; with night-sweats whenever he fell off to sleep, which, however, was not often the case, without artificial aid. In addition, he was harassed by an almost continual hacking cough, though the stethoscope fortunately detected no very particular signs of disease of lungs. He was of pre-eminently scrofulous disposition, with fair skin, showing every vein over his chest, forming a net-work which was very remarkable, excessively irritable, and with large head, and evidently superior intellectual development. His appetite was on the whole good, though variable. He was ordered full and extra diet, with wine and ale. The gangrene had extended above the ankle, and had nearly separated.

Finding, when he had been in the house a week, that he was losing rather than gaining ground, Mr. Luke determined to operate; not, however, I think, without considerable reluctance, the case being about as bad as could well be looked for. The operation was performed, as in the last case, it not being, however, easy to make flaps, from his extreme emaciation. Being evidently a determined lad, he bore the operation well; and on Mr. Luke's

* I mention the time occupied merely that a better estimate may be formed of the shock to the constitution.

asking him afterwards if he would like a glass of wine, said, "Yes, I will take one, sir, if you will take one with me."

On the second day after the operation severe diarrhœa came on, and several aphthæ formed around the tongue, and he became very much depressed, but rallied again, and then regained his flesh with very great rapidity. The stumps healed almost throughout by adhesion, and in a very few weeks he left the hospital quite *en bon point*.

3. The third was a patient of Mr. Andrews, a man of between 40 and 50. The disease had here also originated in fever, I believe. He was not in so great a state of prostration on admission as the former cases. The gangrene had only extended up to the ankle-joint, and the feet were easily removed by cutting the tendons with a pair of scissors. The stumps not proving any very great source of irritation, it was thought better not to operate till he had more thoroughly recovered his strength. In due time the operation was performed, and he got well without any other inconvenience than a little exfoliation; having necessarily, however, from the mode of treatment adopted, been much longer in the hospital than the other patients.

It was a painful sight to see these three poor fellows lying together in one of the small wards of the hospital; but the good result of the cases is an encouragement to the performance of double operations.

I may mention that there was another case of gangrene of both legs in the hospital at the same time. This was a case of senile gangrene in an old and diseased woman; and of course, under these circumstances, no operation could be thought of.

COLLEGE OF SURGEONS.

Wind, S.W.

Except the 29th and following day, generally cloudy, with frequent and heavy showers of rain. Rain fallen, 1 inch and 4025th of an inch.

HURRICANE.—On the morning of Monday, the 29th, from three to four, the wind blew with the most alarming and tremendous force, uprooting many trees, and doing much damage to the roofs of houses; new and unfinished buildings were in several instances completely thrown down. It appears to be the general opinion that the violence of the wind, which was at its height shortly before 4 o'clock, is unprecedented. During the day the wind had been variable; from five to nine in the evening, S.E. and S.W.; judging chiefly from the nature of the devastation, we should say that the hurricane must have been from the S.W. Nearly 5th of an inch of rain fell between seven and ten on the evening of the 28th, with a gentle breeze from the S.E.

LECTURES ON SURGERY,

DELIVERED AT ST. THOMAS'S
HOSPITAL,

BY THE LATE MR. CLINE;

With Notes.

[THESE lectures were written by Dr. Wilkinson when attending Mr. Cline's lectures, in the years 1787-88-89.

Extract of a letter from Dr. Wilkinson, dated Feb. 6, 1838:—"They (these lectures) are the results of six courses of lectures I attended at St. Thomas's, in 1787, 1788, and 1789; and I am in hopes I did not omit any interesting part of Mr. Cline's valuable observations. The one I had the pleasure of giving you is the repeatedly corrected copy."]

LECTURE VII.

Injuries of the Head requiring the Trepan.—Suppuration.—Extravasation of Blood.—Fractures of the Cranium.—Concussion of the Brain.—Instruments used in Trephining.—Application of the Trephine to the Sternum.

The operation of trepanning may be necessary in cases of fracture, to replace any portion of bone, or to remove pus or blood between the membranes. From violence inflicted on the head, extravasations are frequently taking place between the dura mater and cranium, or between the dura and pia mater, which should be removed by perforating the cranium, otherwise the pressure impedes the function of the brain, producing symptoms which go on increasing, till at last they are fatal. Also from injury, inflammation is frequently produced in the membranes, which often goes on to suppuration; therefore,

perforations are necessary to let out the matter.

We shall first consider what takes place under circumstances of inflammation, which does not come on till some time after the accident has happened. A blow received on the head, whether attended with a wound or not, and very frequently without fracturing the skull, may be doing considerable injury to the internal parts; perhaps the dura mater is separated in some degree from the cranium, from violent external injury. Inflammation is excited, which does not take place for some days after, or perhaps weeks—sometimes five or six weeks; the patient finds there is pain coming on in his head, becomes feverish, and this is soon succeeded by nausea and vomiting; frequently severe rigors, followed in a few hours by others, at length delirium supervenes, the symptoms go on increasing, and the fever and delirium likewise, at length ending in convulsions and death. This is from the injury to the membranes of the brain having been such, that it did not immediately produce extravasation of the fluids, but gradually excited inflammation of the parts, which progressively extended from one part to another, going on to suppuration, indicated by the severe rigors which take place.

The accumulation of matter in any of these parts must necessarily produce the most violent symptoms, which go on increasing, and generally destroy the patient in a few days, if not soon relieved. In all these cases of inflammation of the membranes of the brain the pulse is not full, but small and quick—a thread-like pulse; the patient's skin is very hot; he becomes extremely restless, and the pain seems to be extended over the whole head. At this time the countenance becomes flushed, the tunica conjunctiva red; there is a wildness in the eyes, soon followed by delirium and rigors. In cases of this kind,

evacuations should be used with great freedom. Venesection very largely—as much as the strength will bear—which will probably somewhat diminish the symptoms at first, but they will return in a few hours afterwards, when a repetition will be necessary; after which, evacuations by the bowels should be produced. Antimonials should be exhibited, as Antimon. Tart. or Vin. Antimon., in small quantities, so as to act as relaxants. In these cases a blister to the head is often attended with very great advantage; for, as there is a direct communication of blood-vessels between these of the scalp and those of the dura mater, by exciting an increased circulation in the vessels of the scalp it will assist in emptying the vessels in the inside; blistering, therefore, should be used after V.S. and purging. If from sickness the patient is incapable of keeping any thing on his stomach, cathartic clysters should be given. If the symptoms are not very soon got under, they quickly go on to the suppurative stage, and generally when a rigor has taken place, evacuations are useless. We are not to trust to this general treatment of the constitution only, but also attend to the part affected. In a case of this kind, though there be no appearance where the injury was received in the beginning, it will be necessary, when these symptoms come on, to examine the scalp in every part; if nothing is discoverable to the eye, we should feel; and if in any one part the scalp feels fuller than in others, or there be any puffiness, that probably is the seat of the injury. Very frequently there is no appearance at all at the time of the accident; these symptoms come on afterwards; then there is a small rising at the part where the injury was received. To ascertain the state of the parts, an incision should be made down to the bone, in doing which we frequently find the pericranium separated from the bone, an indication of inflammation of the dura mater underneath, and a small quantity of serous blood between it and the bone. When there is such appearance, though there is no fracture or apparent injury of the bone, a circular portion should be removed to examine the state of the membranes underneath. If there has been no delirium nor rigor, the simple incision, by producing a discharge of blood from the part, may be sufficient, with evacuations, &c. Where the injury externally has been such that there is no appearance of contusion or wound to direct you, you may readily know where to make the opening by feeling the parts. If there should be no puffiness, yet if any one part be more painful than another on pressure, or where there is an increased degree of heat, that will be some guide where to make the

opening. If the pericranium is found in the least separated from the parts underneath, probably the dura mater opposed to that part has suffered, there being such a connexion between the two, that the dura mater is never injured without the pericranium being affected in consequence.

When a circular piece of bone is taken out, and pus is found underneath, and extending beyond the part you have removed, another portion should be removed, till you have exposed the whole surface, to prevent the possibility of any matter being confined underneath, which would prevent the symptoms being abated. Sometimes in cases of this kind, when they have been neglected, patients will go on for some considerable time after suppuration has taken place, and survive the accident many weeks, of which I know one remarkable instance.

Another injury to the head that will require the operation is *extravasation of blood* taking place, where the symptoms come on much sooner than from inflammation. A person receiving a severe blow on the head may immediately at the time suffer a slight inconvenience that may go off, but in a few hours afterwards he finds some pain coming on in the head; at last becomes sleepy, comatose; great diminution of the senses; vision and hearing become greatly impaired. When these symptoms of oppression of the brain come on in a few hours after the accident, there can be no doubt of its arising from extravasation of blood between the dura mater and cranium. Sometimes it does not come on for several hours, at others in half an hour afterwards, according to the number and size of the vessels separated. Here you have not the same small thready pulse as in inflamed membranes, nor so hard, but rather a slow full pulse. In cases of this kind the head should be examined; if there be no wound or contusion, we should examine all over the scalp, to see if any one part is thicker than another. If this is discovered, we should at that part lay bare the bone, and immediately perforate it. If the symptoms are moderate, venesection and evacuations may suffice. If in making a perforation the blood should be situated between the dura mater and cranium, then you have an opportunity of removing it; if extending beyond where you have opened, it should be traced to its extent. In this and all other injuries of the head the patient should be freely bled. This is laid considerable stress on by Mr. Pott; he says it is never known to what extent the injury may have gone, or what injury may arise afterwards. There are many instances of timely evacuations preventing such an

effusion of blood as would otherwise happen, or inflammation from coming on at all. Such patients should be particularly attentive to their mode of living after this time, not using excess in diet or exercise, or any thing that will increase the circulation, for several weeks after; not that such evacuations will at all times prevent the mischief, or from all the attention that can be paid by the patient respecting diet, exercise, &c.

The injuries which may happen to the bones of the cranium are those of *fissure* and *fracture*. By a fissure is meant simply a small crack in the bone, with a hair-like appearance, the division of the bone being so fine; and it is common in all fractures to have a part thus fissured. But it is of more importance to distinguish between fractures attended with depression and those without. The former is where a portion of bone is driven inward below its common situation, consequently making pressure on the membranes. It is sometimes difficult to distinguish a fissure from a suture or natural appearance; as on the os frontis, where, from the passage of small blood-vessels and the frontal nerves, they form small lines which make an indentation on the surface, appearing very much like a crack on the bone; and such has been mistaken for a fissure. It has been observed that fissures may be distinguished from sulci by the irregularity of their edges. The edges of a fissure are always irregular, forming a sharp and rather irregular edge; but in a natural sulcus, the canal is small, and has a smooth round edge: thus I believe they may generally be distinguished, but in some instances it is difficult. Authors have given a rule by which they may be distinguished—viz. by smearing the bone over with a little ink; if you can wipe it off the surface, it is a sulcus; if a fissure, the fluid penetrates so deep that you cannot wipe it out. However, this distinction between a fissure and sulcus is not of considerable importance; for if we have symptoms that require a perforation of the cranium, though there is no fissure, it is no reason why we should not perforate the bone. Many authors of very good authority have laid it down as absolutely necessary to perforate the bone where there was the least crack, under an idea of it extending through the bone, and that the fluid extravasated would get between it and the dura mater; but it is more probable in this case that the fluids should pass through the crack externally, than between it and the bone where it adheres throughout.

In cases of fracture where there is a division of the edges of the bone, it may be a question whether the operation should be performed or not. Many have

insisted that it is not absolutely necessary; but from long experience this may be doubted. Mr. Else's practice was, when there was a fracture of the bone unattended with any symptoms of inflammation, not to take out any portion,—and there were many instances of these patients doing well. Mr. Cheston, of Gloucester, and many others, have adopted the same practice with the same success; for a fracture of the bone simply is of no other consequence than the fracture of any other bone; the injury depends on the mischief done to parts underneath. What I have been now saying is only applicable to fissures and fractures unattended with depression.

There may be depressions independent of fractures in very young subjects. Where there is a depression I am inclined to think the operation should be performed, even where there are no symptoms of inflammation. I have very lately seen a boy who was about 12 or 13 years of age, brought to me to examine his head several weeks after receiving the accident—a very severe blow on the part: this had produced no wound. When I came to examine the part, there was very evidently a fracture, with depression of part of the parietal bone. Several weeks elapsed without my hearing that he ever had any bad symptoms. Some few other instances may be met with where patients have recovered with depressions of the cranium, but I believe they are very rare.

The operation should be performed in the beginning, as it is not in itself to be considered as attended with any danger, though certainly painful; for if the dura mater is not injured in the operation, there would be little doubt of the patient recovering from the operation itself; for merely exposing the surface of the dura mater is not productive of any inflammation that will extend beyond that part; and the outer surface of the dura mater is favourable for healing. I remember some time since a patient of mine who had a considerable depression of part of the os frontis, on whom I performed the operation, and brought the depressed part into its situation, and he got well without any bad symptoms.

Fractures of the cranium are very various in their situation and extent. In young subjects they are generally more extensive than in adults, even from the same degree of injury, probably from the compactness of the bone in the latter, which prevents the fracture from extending so far; also, from the thinness of bone in young subjects, and its fibrous texture: thus on an injury being received it is more likely to extend along the course of its fibres, and to a considerable distance from the part

receiving the injury. I have known it extend from the middle of the occiput to the orbit. If a child receives a blow on the parietal bone, the fracture will extend in several directions, in radiated lines from the part where the injury was received; this is rarely the case in the adult, the bones being much more compact, and the fibrous texture almost entirely lost. I have in more than one instance known a fracture extending in a direct line through the parietal bones, according to the course of its fibres, cross the os frontis, down to the orbit. From this circumstance of the bones being of a fibrous texture, when once you find a fracture you may pretty well judge of the course it will take; for if a blow was received on the middle of the forehead, it would not extend upward and downward, but transversely, that being the direction of its fibres.

Fractures are not uncommon at the basis of the skull, from patients falling immediately on the summit of their head, with little injury of the scalp; these patients go on, with the symptoms becoming gradually worse, whereby they are destroyed. The basis being the weaker part, if force is applied to the summit, the basis will be the most likely to be fractured, especially if a person falls on a soft body. When we can discover a depressed portion of bone, it should be carefully traced to its extent, if in such parts that we can trace it by removing the scalp; it cannot be followed at the basis. It is generally better to trace the fracture before you perforate the bone. If there is depression, the circular piece to be removed should be in the most convenient place for raising it up. The instrument should not be applied on any part that is loose, but at a small distance. In these injuries, every now and then, there are detached portions of bone which should be removed; but these are sometimes so situated, from being lodged or wedged underneath others, as to be difficult to extricate, more especially where the internal table is fractured to a greater extent than the outer. There are some instances, though rare, of the bone being depressed without fracture; but I believe this is only in very young subjects, when the bone is so thin as to yield to pressure. A blow being received on the head of a young child will sometimes press the bone inward. In such a case, when there is no symptom of injury, we should attempt to replace it by drawing the scalp outward, which may be done by a piece of good adhesive plaster soon after the accident. If, on the contrary, it is suffered to remain, it is liable to produce afterwards symptoms of injury; if not, it will produce considerable deformity.

Besides these injuries we have another called *concussion*, or *commotion*, the symptoms of which differ from either of the former. By a concussion of the brain is meant such a degree of injury as to produce symptoms immediately after it is inflicted—where the shock is so great as immediately to produce a cessation of the functions of that organ; this is very frequent, and often complicated with other injuries of the brain. Immediately on receiving the accident the patient becomes senseless, and remains so for some time, in which case he sometimes remains so for days and weeks, and afterwards recovers. Such symptoms, which take place immediately, cannot arise from extravasation; but when the concussion is great, it produces temporary derangement of the brain, so as to impede its functions. Voluntary actions cease; the involuntary go on. Sometimes this is of short duration, only a few minutes, when he recovers and recollects the accident. In these cases of concussion or commotion, the immediate symptom is loss of all sense; the pulse is at first generally slow, but afterwards becomes somewhat quicker, most usually attended with nausea and vomiting, also an involuntary discharge of feces and urine. When there is no suspicion of a fracture, venesection, purgatives, diaphoretics, and blisters, should be repeated from time to time, according to the pulse. Mr. Becher, surgeon of this hospital, used to bleed with great freedom in these cases, and often with great success. One patient with concussion of the brain lay in that state for three weeks, during which time he had been bled twenty times, sometimes twice a day. During all this time he lay in a comatose state, from which he afterwards perfectly recovered. Not unfrequently after an injury of this kind some function is impaired. Sometimes there is an alteration in the direction of the eyes, one or both turned rather inward—a degree of squinting. Sometimes patients entirely lose their memory, or become in a state of idiotism. One very extraordinary case I have heard related, of a man who received a concussion of the brain, and remained in a senseless state for a considerable time. He was a native of Wales, and could talk English very well before the accident, but lost the power of speaking it afterwards; yet he had not lost his reasoning faculties. In concussions of the brain, we cannot at all times use evacuations with such freedom: very often the pulse is not a very strong one; in such it will be useful to employ those means which will keep up the exterior circulation, as Dover's powder, antimonials, opiates. In such cases we should always blister the head, keeping it

open, which will tend to prevent inflammation taking place in the membranes of the brain.

It will be necessary, in reference to the operation of trephining, to enumerate those places in which it will be *improper*:—First, in the middle, from the anterior part of the os frontis to the crucial ridge of the os occipitis, on account of the longitudinal sinus. In the os frontis, at a small distance from the orbits, from the situation of the frontal sinus; also where these cavities are formed, the bone being irregular, might endanger the wounding the dura mater; also from the situation of the spinous process in the middle. The sutures are objectionable from the great firmness with which the dura mater adheres to them; but in those cases where it is much more preferable to trepan on the sutures, this should not prevent us; but when you have the choice, it is better to trepan on one side than immediately upon the suture. The parietal bone may be trepanned, except towards the posterior and inferior angle, where there is a foramen for the passage of an artery to the dura mater. The posterior angle is improper, on account of a small portion of the lateral sinus passing over it, which may be wounded. Wounds of the lateral sinus have been thought fatal, but there are instances of patients having recovered; however, as it is productive of violent hæmorrhage, it is better to avoid it. Of the temporal bone, the upper squamous portion may be trepanned, but it will be impracticable below from its irregularity. The occipital bone is unfavourable, on account of the large crucial ridge on the inside; also, from the situation of the large extensor muscles of the head. At the upper and lateral parts the operation may be performed.

The *instruments* used are generally contained in one case:—1st, A knife for scalping. 2d, A ronge to scrape off the perieranium from the bone, laying as much bare as is necessary. 3d, A perforator in a wooden handle, rather than of iron, being easier to the hand; this perforates the outer table, making an aperture sufficiently large to receive an iron pin, which directs the trephine. Having perforated the bone to a sufficient depth, you take out the pin, and go on with the trephine alone, which is better than the trepan. The teeth should be broad, which, though inconvenient from working slowly, yet is of advantage in making a large groove, which is useful for examination, to see whether you have reached the duramater; from having a very narrow edge you would be more liable to wound the dura mater. It is also grooved on the outside, that it may more readily extricate itself of the dust. Some have been made

with large interstices between the teeth, which is found to work well, more perfectly clearing itself, but is attended with the great disadvantage that you get through one part before the other. In the one circumstance it has a very equal boring; but when there are these interstices between, it saws irregularly. Situated in the crown of the trephine we have a pin fixed, to go into the hole made by the perforator. Having made a groove sufficient to steady the instrument, the pin is taken out by a key; otherwise, from its reaching beyond the teeth, it would be liable to wound the dura mater. During the operation you should examine the groove, which is conveniently done with an eyed probe. Having sawed through the bone, you extract it with a pair of forceps. Sometimes there is a small edge left on the sides, to remove which we have the lenticular, to be introduced between the dura mater and cranium, to defend the dura mater; then scrape the edges of the bone to render them smooth. Also a brush, to clean the teeth of the saw occasionally; an elevator, to raise up the depressed portion; also a pair of pincers—a very convenient instrument to take off a pointed extremity of bone, or in an irregular fracture, where there is a projecting portion, within which cannot be removed by any of the former.

Scalping may be done in various ways, either by a simple incision in the parts, or carried in more directions than one, or removing so much of the scalp as to lay the bone bare throughout its whole extent, which last is attended with considerable inconvenience, as it makes a wound very slow in healing; for the scalp is a part so much attached to the bone, that when you remove any large portion the cicatrix must necessarily be as large as the part removed. Of course the process of healing will be slow, and the cicatrix large; it is therefore better not to remove any of the scalp. In all cases of fracture you may make the incisions so as to have no occasion to remove any at all. We should first only make a simple incision on the part supposed to be injured, which will be sufficient if we mean to trepan the patient only in one part. Having denuded the bone, the perieranium should be separated only as far as is necessary for the application of the trephine, for all the outer table of the bone beyond that will exfoliate from the vessels conveying its nourishment being destroyed; then a perforation should be made only a small way through the exterior table, sufficient to receive the point of a pin; we then apply the trephine, having made a groove sufficient to keep it in its place; the pin should be removed. The patient should

be laid on a low table. Having removed the piece of bone, if the matter is discharged by this, we need not proceed any further: if the matter extends further, we should take out more pieces, as far as it goes: if the depression is extensive, it is often necessary to make several perforations to raise the depressed portion upwards, which should be made opposite to, and not upon, the depressed piece. After the part has been thus removed, if you are not apprehensive that there will be a necessity of repeating the operation, the external wound may be brought into contact, and healed if possible by the first intention, which will greatly shorten the time of cure; but when there is a good deal of inflammation of the dura mater, or where there has been a quantity of matter, they should be left apart, laying some lint between, so as to allow a free discharge of the matter; for bringing the lips together would be only confining the pus, and doing further mischief. Sometimes there is fluid situated between the dura and pia mater; either collections of blood or matter formed in this part; in which case it must be evacuated by making an opening. This should not be done without the greatest necessity—without a surety of a fluid situated underneath; and there is frequently a fulness of the dura mater, which is generally a deception; for the opening of the dura mater is attended with considerable hazard, as it is exposing that cavity, and subjects the part to inflammation. Therefore, unless you are perfectly sure that there is a fluid underneath, by its projecting or fluctuating, you had better not wound the dura mater; not but there are instances of patients recovering when the dura mater has been opened.

We have this operation occasionally performed on the *sternum*, directed in those cases when matter is situated in the mediastinum, when a patient has had very severe peripneumonic symptoms, with a painful sensation under the sternum, which is continued some time after the inflammation has ceased, attended with rigors, by which we may expect that matter is formed under the sternum. It cannot be defined well by symptoms; but after it has continued for some time, will be making its way externally, forming an abscess under the integuments: an opening being made, will be found to communicate with another cavity through the bone. In a case of this kind the sternum should be trepanned, removing a portion of the bone, which will not be exposing the cavity of the chest. When carefully laid open, it will granulate from the bottom and heal; otherwise it might remain in a fistulous state for many years.

ON BLOOD-LETTING IN HÆMORRHAGE AND DROPSY.

BY HENRY CLUTTERBUCK, M.D.

[Dr. CLUTTERBUCK's lectures were supposed to have been concluded in our last volume; but it appears that one lecture remains, which we now subjoin.]

It seems at first rather preposterous to speak of blood-letting as a remedy for hæmorrhage or loss of blood; yet such it unquestionably proves to be on numerous occasions. A little reflection on the subject will satisfy you, that there is nothing unreasonable in such a proposal. This admission, you will say, goes to confirm the homœopathic principle of "*similia similibus curantur*." But as this principle is not more generally true than its opposite "*contraria contrariis*," the admission tends but little, in reality, to the support of a doctrine that, considered as universal, is full of absurdity.

Hæmorrhage may be defined—a preternatural discharge of blood from any part of the body, not the result of injury or mechanical violence. Hæmorrhage does not take place indifferently from all parts alike, but is chiefly confined to such as are particularly vascular in structure and delicate in texture; and in which, at the same time, the vessels run superficially.

These conditions are met with in the membrane lining the nostrils and air-passages in general, and especially in the lungs themselves; in the alimentary canal, particularly the extremity of the rectum; in the urinary organs also, which are frequently the seat of this disease; and, lastly, in the uterus, of which hæmorrhage may almost be considered as one of the functions.

In order to understand the use of blood-letting in the different varieties of hæmorrhage, it will be requisite to consider a little the intrinsic nature of the affection in general, or, what is technically termed, its proximate cause. I must premise, however, that the observations I am about to make, apply to what has been called active hæmorrhage, and not at all to those passive forms of the disease (as they have been considered,) in which the blood escapes from the vessels; either owing to their want of contractility, or to the imperfect and dissolved state of the blood itself. Blood-letting, it is plain, can have no application to such.

Now hæmorrhage, of the active kind mentioned, is essentially a local, not a general affection; for although it is sometimes preceded and accompanied by pyrexia,

or a state of general excitement, it nevertheless frequently occurs without any increase of action, or other disorder, either in the heart, or general vascular system. We find it taking place, accordingly, both in the weak and in the strong. Whether the discharge of blood is owing to actual rupture of vessels, or whether it is not attributable (in part at least) to enlargement of the exhaling extremities of the arteries, so as to allow of the escape of blood from them, seems uncertain. It is so often preceded and accompanied by heat, and an increased flow of blood to the part, that it is probable it depends immediately upon an increased action in the capillary extremities of the arteries of the affected part.

The parts peculiarly liable to hæmorrhage are the following:—1st, the nostrils, where the disease takes the name of *epistaxis*; 2nd, the lungs (*hæmoptysis*); 3d, the stomach, from which the blood is usually discharged by vomiting (*hæmatemesis*); 4th, the general tract of the intestinal canal, a discharge of blood from which, though by no means uncommon, has received no particular or appropriate denomination; 5th, the extremity of the rectum (*hæmarrhois*); 6th, the urinary organs (*hæmaturia*); and, lastly, the uterus (*menorrhagia*.) Besides these, which are of the most ordinary occurrence, and where the blood is discharged outwardly, hæmorrhage may take place internally, and is then only known from symptoms, or by examination of the body after death. Thus the heart may burst, or some of the larger vessels in the cavities of the chest or abdomen give way, so as at times to lead to the immediate extinction of life. And the same occurs still more frequently in the brain, giving rise to apoplexy or palsy, or both, according to the particular seat and amount of the blood extravasated. Now blood-letting, though imperatively demanded in many of these cases, is by no means universally proper; and even where it is called for, attention is always required to be paid to the particular circumstances of the case, in order to determine the degree and manner in which the remedy is to be administered.

Let us first speak of the general circumstances that may either call for, or prohibit its use.

When hæmorrhage takes place in persons of full or sanguine habit, and who possess a tolerable share of general strength, when it is accompanied with a febrile state of system (*pyrexia*), and a sense of fulness and distension in and about the part from which the blood flows, or is about to flow, an antiphlogistic mode of treatment is very generally called for, in all respects analogous with that of inflammation, to

which, indeed, hæmorrhage nearly approaches in its general characters, and into which it often passes. It is here, if ever, that blood-letting is required; not, however, for the purpose that has sometimes been assigned to it, namely, that of diminishing plethora, but (as in inflammation) with the double object of directly reducing the arterial action of the part; and, indirectly, upon the principle of counter-irritation, or rather counter-impression, as before explained to you. In such cases, after blood-letting, other means of producing counter-irritation, such as vomiting, purging, and blistering, may be resorted to with advantage; as well as *astrigents*, which have the effect of producing contraction of the capillaries; and also *sedatives*, for the purpose of allaying vascular excitement, a purpose that is often well answered, both by the *digitalis*, and the salts of lead.

The notion entertained by many, that hæmorrhage is the consequence of plethora, or an excess of blood in the system, leads to uncertain, and even pernicious practice—uncertain, because, supposing such a state as plethora to exist, which is at least doubtful, it is impossible to estimate its degree—and pernicious, because it inculcates the employment of blood-letting in many cases to which it is not at all adapted, but rather the contrary. In a late elementary treatise on the *Materia Medica*, the author remarks “that it is unnecessary to draw blood artificially, because the hæmorrhage will cease as soon as the quantity of blood lost brings down the plethoric state which induced it.” By acting upon this principle, the patient may be brought into great danger; for we often find hæmorrhage continuing, or recurring at short intervals, to an enormous extent, and in spite of the most liberal use of the lancet, till the system is nearly exhausted. Plethora, it is evident, can have no share in keeping up such hæmorrhages. But, in fact, the object of blood-letting in hæmorrhage is not that of simply diminishing the quantity of blood in the system; but for checking the action of the bleeding vessels, upon the principle of counter-impression, as before explained. The effect, as in the case of inflammation, depends more upon the mode of drawing than upon the quantity of blood lost. And thus hæmorrhage will be checked at times by the sudden loss of half a pound of blood, a quantity that can have no appreciable effect in lessening the bulk of the circulating mass.

When hæmorrhage takes place without febrile symptoms, or when these have subsided; and where the system altogether is weak, either originally or from the continuance of the discharge; where, again,

the pulse is soft and feeble, the skin pale, and the solids soft and flabby, with cold extremities, blood-letting can hardly be either necessary or even safe. In such cases astringents of different kinds, and even the most active general stimulants, are required.

The treatment of hæmorrhages varies considerably, according to the part affected; it becomes necessary, therefore, to speak of them individually; for blood-letting is not equally adapted to all.

In epistaxis, local remedies are of more avail than general ones. Blood-letting is not called for unless there be much throbbing of arteries within the head. Cupping from the back of the neck may, however, be useful, upon the principle of counter-irritation; as also purging and blistering upon the same principle. Should the application of cold to the face not have the desired effect, the snuffing up some active stimulant, such as alcohol, a little diluted, or inhaling the vapour of ammonia, or of the oil of turpentine, would be likely to succeed. Plugging the nostrils is another, though uncertain mode of restraining the hæmorrhage. Sometimes the bleeding orifice is so low down as to be closed by simply compressing the nostrils.

In the treatment of hæmoptysis, blood-letting is often injudiciously administered, and without sufficient discrimination. You should consider the object to be attained by its use, before having recourse to it at all. Bleeding can only restrain hæmorrhage from the lungs, either by lessening the vascular action in general, or that of the lungs in particular. But the general vascular action is not always increased in cases of pulmonary hæmorrhage: and bleeding, therefore, is not necessarily required for such a purpose. In almost all cases of hæmorrhage from the lungs, there is more or less of disorganization, the result of previous inflammation, and which is the real source of the danger to be apprehended. The object of bleeding is to relieve this, and not merely to repress the hæmorrhage, which, of itself, is in most cases of little real importance, and if not going to excess, tends rather to give relief. There is generally an unnecessary degree of alarm felt in these cases, and which frequently leads to improper practice. It is very rare, in cases of hæmoptysis, for the hæmorrhage to go to a dangerous extent. In a few instances, no doubt, it proves immediately fatal, by the blood being poured out so rapidly as to fill the bronchial tubes, so as to occasion suffocation. But such a circumstance cannot be foreseen, nor has blood-letting any power to relieve it. It is not an uncommon practice, in cases of hæmorrhage

from the lungs, to expose the naked body of the patient to cold air; or to apply cold water, or even ice, to the surface of the chest. But the effect of this is, by contracting the external vessels, to throw the blood in greater quantity upon the lungs, so as to produce distension of vessels there—a most likely cause of increasing the hæmorrhage at the moment, and of aggravating the local inflammation afterwards. It would be far more advisable to keep up an equable circulation, by friction, external warmth, and even the use of internal stimulants—a practice that I have often seen successful, and the good effect of which is enhanced by making the patient breathe an artificially-cooled atmosphere; as by inhaling from a vessel containing ice.

It is not foreign to the purpose to remark here, that I much question the utility of confining phthysical patients to close apartments, for the purpose of breathing a regulated atmosphere; and that at rather an elevated temperature, as is usually the case. The general circulation is thus liable to be increased, and the hectic disposition aggravated; than which, nothing is more likely to accelerate the progress of the disease. It is doubtless an advantage to preserve an equal circulation over the whole body, with the view of preventing a disproportionate accumulation of blood in the lungs: but this, according to my observation, is best accomplished by warm clothing, and the use of substantial food, as the appetite may require. Nor is the moderate use of stimulants objectionable in such cases, in the winter season. Now while the general circulation is thus maintained in *equilibrio*, that of the lungs themselves should, as far as possible, be restrained—an object that is best attained by the inspiration of cool air. If, therefore, the patient is to be confined to a regulated temperature, the air he breathes should be as cool as is consistent with his comfortable feelings, so as to avoid a sense of chilliness. But I am inclined to believe, from observation, that a much greater latitude than is usually conceded might be adopted in these cases, not only without disadvantage, but with benefit to the patient upon the whole. Over-great care generally defeats its own purpose; by increasing the susceptibility of the body to all impressions. I think I have observed that those phthysical patients do best upon the whole, who are the least fastidious in regard to atmospheric exposure, as well as various other supposed noxious agents. I have known a phthysical patient bathe daily in the open sea throughout the winter; and, according to his own conviction, with decided benefit.

It is true that the disease, in this instance, as is too generally the case, proved ultimately fatal ; but after a longer duration, and apparently with less suffering, than in most other cases I have witnessed.

As an important part of the treatment of phthisis pulmonalis, and of hæmoptysis also, as a frequent attendant on this, I would strongly recommend the inhalation of an artificially-cooled atmosphere in the manner I have just hinted at ; and that repeatedly in the course of the day. If this, with other parts of the regimen before described, be had recourse to, you will have little occasion for, or rather, I should say, may advantageously dispense with, a farrago of drugs that are usually employed in these cases ; always excepting, however, the digitalis, and an occasional small bleeding, the advantage derivable from both which, as sedative or antiphlogistic means, are easily understood, and cannot well be over-rated.

Hæmatemesis, or vomiting of blood, seldom occurs spontaneously, unless in the rare case of its being vicarious with menstruation. It is mostly the effect of organic disease of the stomach itself, or of some neighbouring part, and which, of course, is the result of slow and destructive inflammation. The organic mischief, wherever seated, is of so slow a growth, and so commonly accompanied by general weakness, that there is seldom any call for blood-letting, and only as an occasional palliative. Much the same may be said of a discharge of blood from the intestines. The blood discharged in these cases is usually dark-coloured, and sometimes nearly black, (*melana*), from its long remora in the canal previous to its discharge. Affections of this sort, of long standing, as they commonly are, seldom require or admit of blood-letting.

Hæmorrhoidal affections attended by loss of blood, (as the name implies) are so generally accompanied by local disease in the part, without disorder of system, that local remedies, including topical bleeding, are, for the most part, all that is required.

Hæmorrhage from the kidneys seldom occurs, except as the result of the presence of renal calculi ; to which blood-letting has no application, unless from the casual combination of active inflammation.

Of uterine hæmorrhage.—Uterine hæmorrhage is distinguished from epistaxis and hæmoptysis, by the muscular contractility possessed by this organ, the uterus, a circumstance which on many occasions materially influences the result of the disease. Thus, when the uterus is in a distended state, as in pregnancy, and the blood-vessels have become enlarged in consequence, the contraction of the organ tends to compress the vessels, and thereby

to restrain the bleeding from them. In all cases, therefore, of uterine hæmorrhage, occurring in such circumstances, it is of importance, when otherwise practicable and proper, to remove the distending cause, so as to allow of the contraction of the uterus taking place. On this ground, it is often found necessary to effect the removal of the fœtus, or of the placenta, where this happens to be retained. The obstacle to the contraction of the womb being thus removed, the contraction itself may be promoted by appropriate means ; such as pressure over the abdomen, the application of cold, and mechanical irritation of the os uteri itself. Now I hardly need observe, that this is not a case of hæmorrhage in which blood-letting can generally be required. But all this involves a variety of considerations, with which we have here no concern. In other cases of uterine hæmorrhage, unconnected with gestation, the propriety of having recourse to blood-letting must, of course, be determined by the circumstances present. These may be such as to require the use of this remedy ; as where the habit is strong, and signs of inflammation exist. But where the general strength is exhausted from the long continuance of the hæmorrhage, a different treatment is required : of which the following case affords an instance :—A woman, after suffering a miscarriage, had frequent returns of hæmorrhage during seven weeks, when I first saw her. She had been bled freely and repeatedly, and the usual astringent remedies had been employed, but without the desired effect. She had become pale—the pulse was soft and weak—and the extremities cold. Three drachms of the compound Tincture of Cinnaomon, with one drachm of the Spiritus Ammoniac, a little diluted, were given every four hours. This excited much feverish heat and thirst. The hæmorrhage soon ceased, and did not again recur. I have used the *Ol. Terebinth.* in other cases of the sort, with equal advantage. Some practitioners, I may observe, have recommended a large use of opium, in cases of uterine hæmorrhage immediately following parturition ; but upon what just grounds it is difficult to perceive. Opium is powerful in lessening the disposition to muscular action in general, and so far seems calculated to prevent that contraction of the uterus which is the chief means of suppressing the hæmorrhage in such cases.

An equal objection, as I think, applies to the use of brandy or other spirit, which it has been the fashion of late to administer to an enormous extent to patients so circumstanced. Now alcohol, when largely employed, has nearly the same effect as opium in diminishing muscular

power. They are both narcotics. And although spirit appears to be more stimulant, with respect to the action of the heart and sanguiferous system altogether, its effect in this way is not lasting, nor can it be kept up for any length of time; so that no permanent advantage is gained by it. An appeal is made to experience here, as deciding in favour of the practice. But nothing is so fallacious as what is called experience. It is, in fact, little more in general than individual opinion, and practitioners, I know, are much divided on the subject. All I wish to say is, do not hastily adopt opinions on this or any other subject.

Of the Use of Blood-letting in Dropsy.

As with regard to most other medical subjects, you will find a great and lamentable diversity of opinion among writers, not only with respect to the supposed nature and mode of production of dropsy (what we call the theory of the disease), but, which is of far greater moment, the treatment proposed for its relief. Thus, the notion of debility is almost universally coupled with dropsy; in consequence of which, blood-letting, as a debilitating power, is particularly dreaded, not merely as incompatible with the nature of the disease, but as tending, in fact, to its production. Under this apprehension, the use of this remedy is avoided on numerous occasions where it is urgently required. On the other hand, it is sometimes asserted that bleeding cures dropsy. But neither of these opinions is true in the abstract. Bleeding has no direct tendency to produce dropsy; nor, on the other hand, does it directly cure the disease, although its employment is often strongly called for. To understand all this, we must look a little to the origin of the disease, and the manner of its production.

Dropsy is a preternatural accumulation of serous fluid in any of the cavities or interstices of the body; and, of course, the seat of it may be very various. It may take place, for example, in any of the close cavities of the body—as the abdomen, thorax, or cranium; as well as others, which it is needless to particularize, because the same general principles apply to all of them. These have been sometimes termed encysted dropsies, in order to distinguish them from that diffused or cellular species where the fluid is lodged in the cellular or reticular membrane that connects the skin with the subjacent parts, and contiguous organs with each other. This variety of dropsy only differs from the former by the circumstance of the fluid readily passing from one part to another, by gravitation or pressure, in consequence of the free

communication that exists between the different parts throughout the whole cellular structure.

Now there is constantly going on, in health, a secretion or exhalation of fluid from all the surfaces mentioned, in quantity just sufficient to keep those surfaces moist; while the fluid thus thrown out is as constantly taken up again by the absorbents, and carried into the veins, by a route which you are of course acquainted with. Thus, exhalation and absorption are balanced, and there is no accumulation in any of the cavities or interstices of the body. But if either of these functions should be materially disturbed, so that exhalation should much exceed absorption, accumulation necessarily takes place, and dropsy is the result. So far, there is no uncertainty; but with regard to the precise way in which the accumulation takes place, in different instances, there is much difference of opinion; and as the question of treatment, especially in regard to the use of blood-letting, becomes involved, we must go further into the inquiry.

There are different ways in which the accumulation may take place in dropsy. For instance, exhalation may be morbidly increased, absorption continuing as before: in this case, the exhalents are in fault. Or exhalation taking place in the ordinary degree, absorption may be defective. It may even happen that both exhalation and absorption are either in excess, or deficient, at the same time; and yet, provided the former exceeds the latter, accumulation will be the consequence. These, however, are cases that can hardly be distinguished in practice. But it is of consequence to determine, in a general way, whether, in any particular instance, the dropsical accumulation is owing to increased secretion or exhalation, or to diminished absorption; for the treatment will differ widely, according as the one or the other happens to be the immediate cause of the accumulation. In order to determine this, we should inquire into the causes and circumstances that can occasion either increased exhalation or diminished absorption; for the treatment must be adapted, as far as possible, to the one or the other, as it may happen to prevail.

The most frequent cause of increased exhalation from surfaces appears to be the increased circulation that not merely accompanies, but seems to make an essential part of inflammation. There are, indeed, very few cases of dropsy where a connexion with, and dependence upon, inflammation may not be distinctly traced; of which, thoracic dropsy, both of the pleura and pericardium, affords the most striking proof. This is scarcely less ob-

vious in regard to the cavity of the skull; where inflammation of the membranes obviously lays the foundation of all the more acute forms of hydrocephalus. In the abdomen, also, the same will be found, upon careful inquiry, to be the case; and if the presence of inflammation is less obvious here than in the thorax and cranium, it is because the functions that are carried on in the abdominal cavity are not so immediately important to life as in the other cases; the symptoms altogether are, therefore, less urgent, and less striking. The same effect of inflammation in producing increased exhalation is observed with regard to the cellular texture in general; much of the swelling that takes place on such occasions being attributable to this circumstance.

But it is not the most acute degree of inflammation, in any case, that has this effect: adhesion of the inflamed surfaces more commonly then happens, and the cavity is in consequence wholly or partially obliterated; while, in the case of the cellular membrane, the part is condensed and indurated, so that the natural texture is destroyed.

Now it is in dropsies connected with inflammation, in the way I have just described, that blood-letting, as well as other antiphlogistic remedies, is occasionally called for. In all cases of dropsy, therefore, that are submitted to your care, you should inquire first, whether they are founded in inflammation, and whether the inflammation still exists; and, secondly, whether the stage of the disease, as well as the other circumstances of the case, are such as to justify the use of this remedy.

The determining the former question is seldom a matter of much difficulty. The signs, both local and constitutional, of existing inflammation, are, in general, too obvious to be mistaken. With respect to the latter, or constitutional signs, much stress has been laid of late years upon the circumstance of the presence of albuminous matter in the urine of dropsical subjects, as serving to shew the particular character of the dropsy, and as affording indications with regard to the treatment. But the albuminous state of the urine is not peculiar to dropsy; it is rather characteristic of certain degrees of inflammation, whatever the organ be that is so affected. Nor is it decisive as to the employment of antiphlogistic means of cure—at least of blood-letting—for this must be governed by a general view of the circumstances of the case, as I have frequently before pointed out.

Much, also, has been said and written of late about a peculiar change of structure in the kidneys, and which consists chiefly in a granulated texture of the or-

gan. This was first, I believe, particularly noticed by Dr. Bright, and is now familiarly termed by writers "Bright's kidney," such a degeneration of the structure being supposed the immediate cause of the secretion of albuminous urine. But there are many objections to this hypothesis, and which have been particularly pointed out by Dr. Graves, of Dublin, in his clinical lectures as recently published in the *Lancet**. In the first place, an albuminous state of the urine may exist without such a condition of the kidney; and where it really exists, the urine at one time presents the albuminous appearance, while at another this is wanting. Albuminous matter is deposited, also, in the different cavities of the body in dropsy, as well as occasionally secreted by the kidney. The connexion, therefore, that is contended for between "Bright's kidney" and albuminous urine, can hardly be maintained. As far as I have observed, the presence of albumen in the urine is only found where febrile symptoms are present; and as the febrile state is always the result of inflammation, such a state of the urine serves only to prove the frequent connexion of dropsy with inflammation as its most general source.

Supposing, then, that either by local or general signs the existence of inflammation is shewn in any case of dropsy, we have to determine the propriety of bleeding by the stage of the disease and the general condition of the patient, in respect of his general strength and other circumstances, just as in ordinary cases of inflammation. If the disease is recent, and the habit tolerably strong, blood-letting is not only unobjectionable, but highly useful, and even often indispensable to the cure. It is in hydrothorax, perhaps, more than in any other variety of dropsy, that the inflammatory character is the most marked, and the advantage of blood-letting most frequently and distinctly seen. It is not a large abstraction of blood, however, that is wanted, nor, in fact, would such be safe. The irritability of the heart is so morbidly changed in these cases by the inflammation, that any great disturbance of its action, such as a large or sudden abstraction of blood is likely to produce, might prove immediately fatal. This does not apply to the deliberate loss of from four to six ounces, which, under the favourable circumstances mentioned, seldom fails to be followed by decided relief; while, provided the stomach is capable of performing its office well, many repetitions of the evacuation, with a few days' interval, may be borne with perfect safety, and, in not a few instances, with an abso-

* See the *Lancet* for October 20, 1838.

lately curative effect, as I know from experience.

Many cases of general anasæra arise from thoracic inflammation, as is clearly proved by the symptoms; and the way in which the dropsy takes place is probably this: the thoracic duct becomes obstructed, either by participating in the inflammation, or from being pressed upon by the swelling of the neighbouring parts. The necessary effect of this is, first, impeded transmission; and, next, a cessation of the process of absorption. Blood-letting probably effects the cure of such a disease by putting a stop to the thoracic inflammation, the swelling produced by which gradually subsides afterwards. Such a gratifying result I have often witnessed in recent dropsies of this description.

Cranial dropsy, when recent, is also very generally accompanied with signs of inflammation, this being in reality the foundation of the effusion, as it is termed. A cautious antiphlogistic treatment is the only one likely to prove successful.

A not unfrequent variety of dropsy is that which follows scarlatina. This probably results from the previous inflammatory state of the skin and subjacent cellular texture, just as happens in various other inflammations. It is usually observed upon the decline of the febrile symptoms, but often before they have wholly subsided; arguing, therefore, a continuance of the inflammatory state. The idea of debility has been attached to this kind of dropsy as to most others; and tonics and stimulants of various kinds have been liberally administered, in accordance with this notion. This practice has generally appeared to me not only useless, but injurious, by aggravating the febrile symptoms, and keeping up the inflammatory state of the subcutaneous membrane. Generally speaking, medicine is superfluous in these cases, the disease gradually and spontaneously disappearing. If, however, the febrile symptoms run high, and the tongue is foul and dry, a small bleeding or two, in proportion to the strength of the patient, with purgatives and the digitalis, are of essential service.

You may easily transfer the mode of reasoning here employed to other varieties of dropsy, so as to deduce from it the proper mode of treatment. It is but too true, that few cases of dropsy are, or can be, cured. The reason is, that the disease in most instances is accompanied with so much visceral disease, as to defy the power of art. Much, however, of our want of success in the treatment of dropsy is owing to the neglect of inflammation in its early stage. Prompt and active blood-letting prevents dropsy in numerous instances, by putting a stop to the inflammation, which

is, in a large proportion of cases, the real origin of the disease. Properly speaking, bleeding does not cure dropsy itself, but effects its purpose by removing the general cause—to wit, inflammation. I have never seen reason to believe that blood-letting, to whatever extent it be carried, produces real dropsy. The notion is, that it impoverishes the blood, rendering it more watery in consistence, and so thin as to be incapable of retention in the vessels. Now that repeated loss of blood changes the relative proportions of the component parts of the mass is no doubt true; the serous parts becoming augmented, while the crassamentum is diminished in proportion; and so far the blood presents a more watery appearance. But there is a fallacy here. On many trials, I have found that the abundant serum in these cases coagulates as entirely by heat and other agents, as it does where it makes a smaller proportion of the mass, which is therefore not so watery as it looks. There is less of fibrin, but not less of albuminous matter present. That dropsy, therefore, is producible to any formidable extent by blood-letting, I am inclined from observation to deny. An *œdematous* state of the lower extremities may thus take place in a slight degree, not owing, however, to the circumstance mentioned, viz. a more watery state of the blood, but to a weaker action of the absorbent vessels, by which the return of lymph from the extremities is impeded. This is seldom observed but in the lower extremities, and chiefly after they have remained for some time in a dependent position.

Upon the whole, you need not be deterred from the employment of blood-letting in any case of active inflammation, from the apprehension of its inducing dropsy; this disease, on the contrary, often arises from the neglect of it.

Some have ascribed dropsy to a torpid state of the capillaries, allowing fluid to escape from them in greater quantity than the absorbents can take it up*. Upon this ground we are directed to stimulate the capillaries to greater action; and the means recommended for the purpose are calomel, blisters, and the digitalis. But the fluid in dropsy does not ooze out from the pores or extremities of the vessels, but is the result of secretion, which is a vital process, and likely to be retarded rather than promoted by a diminution of action in the capillaries. The means of cure here alluded to may no doubt be useful on some occasions, though not upon the prin-

* See an account of Clinical Lectures delivered at the North London Hospital, by Fr. Thomson, Professor of Materia Medica in University College: *Lancet*, Jan. 4, 1838.

ciple supposed. The digitalis seems strangely classed with stimulants, for the purpose of exciting the action of the capillaries; but then it is said, in the way of explanation, that digitalis is a stimulant at first, but that when it is accumulated in the system to a certain extent, then it becomes a direct sedative. This to me, I confess, is not very intelligible.

I mentioned that dropsy, though generally the result of increased secretion or exhalation (as when it arises immediately as a consequence of inflammation), nevertheless is in some cases owing to deficient absorption, or—which soon comes to the same thing—impeded transmission of the lymph from obstruction of the absorbent vessels. This I instanced in the case of inflammation in the chest producing obstruction in the thoracic duct. A similar cause of obstruction may occur in other parts of the absorbing system, and with similar effect. The removal of the obstructing cause, whatever it be, is for the most part essential to the cure of such dropsies; and blood-letting is only applicable so far as it is capable of removing such cause. This you will readily understand from what has been already stated.

ON EXTERNAL PRESSURE IN PROLAPSUS UTERI.

By JOHN F. GRAY, M.D.

Of New York.

(For the *London Medical Gazette*.)

PROLAPSUS uteri has two essentially distinct forms, one of which has not been sufficiently noticed in our manuals of female diseases; I allude to a dislocation of the womb downward and slightly backward, the os tincæ tending toward the coecyx. The ano-perineal region of Velpeau, or the perineum posticum of the older anatomists, from relaxation of the levator and sphincter ani, becomes enlarged, and the triangular space between the point of the coecyx and the tuberosities of the ischian bones forms, in consequence, a broad deep *cul-de-sac*, into which the uterus sinks in the line of its own axis, and rests against the anus and rectum.

This posterior dislocation of the womb often takes place in pregnancy, particularly during the first four months; but it also takes place under other circumstances, I have no doubt, and that much more frequently than is commonly supposed.

Sir Charles Clarke* speaks of the uterus descending against the perineum, and there resting as upon a shelf. I have seen very many cases of this kind, in which there were vaginal discharges of various kinds, frequent false calls to go to stool, vesical irritation, and dragging pains in the lower part of the back and groins, from the utero-sacral and round ligaments being put upon the stretch.

Indeed, I believe nearly every case of confirmed fluor albus, not connected with the prolapsus of the books, is accompanied by this form of uterine displacement. If from an uncommon curvature of the sacrum backward, a large pelvis, increased volume of the uterus, relaxation of the ligaments, or any other cause, the ano-perineal region may be large enough to receive the impregnated womb as late as the seventh month†, and if retroversion of that organ does frequently take place after labour and after miscarriage, why should there not be procidentia or delapsus uteri in that direction as frequently at least as in the other? There exists, as far as I am aware, no anatomical impediment to the posterior dislocation, and the uterus, under the depressing forces of the abdomen, as in the act of defecation, must, it should seem, always tend toward the perineum posticum; and if the utero-sacral ligaments are somewhat more relaxed than the recto-vaginal septum, the fundus uteri would fall forward, and the whole viscus sink downward and backward in the line named, *i. e.* the axis of the superior strait of the pelvis.

The posterior displacement will be readily recognised by examination per anum. The finger will have to pass very much more backward than usual, to get around the os tincæ, which lies hard against the rectum, just above the sphincter ani, and is very perceptible to the feel of the surgeon.

In passing the finger per vaginam, the neck of the womb is first encountered, occupying the situation of the os uteri.

The os uteri is found lying against the rectum, its aspect being backward and downward toward the point of the

* Observations on Diseases of Females, 2d edition, page 62.

† Vide Madame Boivin on Disease of the Uterus, page 73.

os coccygis, and the finger will have to be carried back in a curved form to reach it. The space between the os uteri and the posterior termination of the vagina appears much larger than natural.

In addition to the ordinary symptoms of prolapsus, the patient experiences a sensation, from the pressure of the os uteri against the rectum, of a foreign body lying in the intestine just above the anus, and feels as if she ought to void it by going to stool,—a peculiar tenesmus, the attempt to obey which, of course, only aggravates its cause. Besides this sensation, many varieties of leucorrhœa are dependent upon the posterior displacement of the womb. In fact, discharges from the vagina not traceable to syphilitic taint, and not arising from scirrhus or polypus uteri, are very apt to arise from this cause, and are to be remedied by the application of “Hull’s utero-abdominal supporter,” an external force which will be found to replace the prolapsed uterus with great facility, whether it be of the anterior or posterior species. This posterior dislocation of the womb may very readily be mistaken for internal piles, prolapsus ani, or even stricture of the rectum, and be accordingly maltreated.

Thousands of females afflicted with false disposition to go to stool, inveterate fluor albus, occasional menorrhagia, painful or irregular menstruation, urinary difficulties, dyspeptic symptoms, and anomalous sufferings in the back, loins, and pelvis, have the misfortune to be treated for these symptoms as so many separate maladies, whose cases arise from the posterior prolapsus, and might, by aid of Dr. Hull’s apparatus for the external cure of prolapsus uteri, be speedily alleviated, with a fair prospect of radical restoration to health.

This subject should be carefully attended to in every case. The diagnosis is certainly not difficult, when assisted, or, as I may say, determined, by examination both per anum and per vaginam; and when it is fairly established that the womb has sunk back and down upon or into the ano-perineal region, the application of Dr. Hull’s supporter ought not to be delayed.

The pessary in this case does no good whatever: it is thrust into the ano-perineal region, already rendered *a sac* by relaxation and by the presence of the

dislodged womb, and there, as a really foreign body, excites the same sensations and keeps up the same irritation and discharges which the womb had done, and generally as may readily be supposed, the latter are of a very aggravated character; whereas the new instrument of Dr. Hull, by pressing the ano-perineal region upward and inward, directly opposes the descent of the womb, and at the same time diminishes the capacity of this region, whilst the hypogastric support of the apparatus prevents the descent of the abdominal viscera into the pelvis in a manner I shall hereafter notice. [The cup-and-ball pessary of Baubin, with its spiral spring improved by Récamier, is not much better than the ordinary pessaries. It presses upwards and backwards towards the promontory of the sacrum, and not upwards and forwards in the axis of the superior strait, and therefore does not meet the uterus in a direction opposite its line of descent, but meets it an obtuse angle. I have nothing to add to the ordinary descriptions of prolapsus, but that they only regard those dislocations of the uterus in which its fundus falls downward and backward, and the os uteri traverses the vagina, appearing first at the vulva in complete prolapsus, and presenting first to the finger, in the incomplete or procidentia, and that in so far these descriptions are totally imperfect, excepting the remark quoted from Sir Charles Clarke, speaking of the kind I have described.]

In reference to the causes of the various prolapses of the uterus with the accompanying displacements of the bladder and rectum, I beg leave to state my dissent from the received notions of relaxation of the ligaments of the uterus and the weight of that viscus being the cause of the displacement*.

In the dead body, the uterus cannot be pushed downward, even after an entire division of its ligaments†. And the vagina, which Dr. Dewees supposes to be the main support of the uterus, is always a flexible collapsed passage, except during the moments of orgasmic turgescence. It is, besides, very frequently relaxed, and even inverted,

* Doane’s Good, vol. ii. p. 472; Cooper’s Dictionary; Mad. Boivin; Clarke, &c.

† Dewees’ Diseases of Females.

without being accompanied by displacement of the womb. It seems to me really absurd to suppose the round ligaments, which are considerably curved, and therefore loose (not "tort,") with the duplicatures made by the peritoneum about the fundus uteri, which are certainly far from appearing like real ligaments, would support the womb against the enormous depressing force of the diaphragm and abdominal muscles, if the ano-perineal muscles and aponeuroses were removed; *i. e.* if the ano-perineal were divided and reflected back, or dissected entirely away. That nature never intended these falsely called ligaments to keep the uterus *in situ*, is evident from their presenting no resistance whatever to the ascent of that viscus in gestation. Mr. Pott*, speaking of the proximate cause of hernia, says, "If the cavity of the abdomen is always full completely, the containing and contained parts re-act upon and reciprocally compress each other. It is by the effect of this moderate, but equal and unremitting pressure, that all the viscera mutually support each other. Without it the ligaments of the liver, those of the spleen and the various membranous bands of the intestines in general, would only be feeble means for fixing such parts in their respective situations.

"But there are certain points of the abdominal parietes which naturally present much less resistance than others. Such is, particularly, the part which extends from the pubes to the anterior superior spinous process of the ilium. This relative weakness of some points of the abdominal parietes is very marked in certain individuals, in consequence of a defect of organization. It may also be increased by internal or external causes. The conjoined powers of the abdominal muscles, diaphragm, and levator ani, are then directed and concentrated against the most feeble point of the abdomen, towards which they impel the nearest viscus, or that which from its moveableness is the most liable to displacement."

Thus an equilibrium in the containing muscular forces of the abdomen is fairly shewn to be more essential to the relative positions of the viscera than so-called ligaments are. But Mr. Pott has

not alluded to the important and very obvious antagonism between the muscles of the perineum and the diaphragm, and oblique muscles of the abdomen—a consideration of the greatest consequence in accounting for prolapses of the uterus, or hernia of the pelvis. Velpeau, in his *Surgical Anatomy**, makes the following forcible illustration of this view of the subject:—"The coccygei and levatores ani muscles here form a species of septum of diaphragm, which is a perfect antagonist to the thoraco-abdominal septum." The coccygei levatores ani transversales perinei, covered within by the aponeurotic fascia pelvis (Cloquet), and without by a strong subcutaneous layer or fascia, form a firm muscular septum, which closes the lower outlet of the pelvis, and which, from its moving with every respiratory act of the diaphragm, rising and falling in constant antagonism to the rise and fall of that septum, is certainly aptly called the lower diaphragm. I conceive *relaxation of this perineal apparatus*, whether caused by labours, coughing, lifting, &c., or by actual disease, weakening and attenuating its fibres, to be an essential condition to the existence of displacements of the pelvic viscera. The perineum, by which I mean all the parts enumerated, and they are so recognised by Velpeau and others, has to perform for a large space in the female, a resistance equal to very much of the depressing forces of the upper abdominal parietes: for the rest of the pelvis, being bone, lined with polished fascia, and of the form of an irregular inverted cone, reflects nearly all the forces they receive downward upon it; the only bony assistance it has is afforded by the coccyx, when fixed by its muscles and the levatores ani. If, then, this resistance be diminished, the perineal cavity must be increased, and the uterus must sink down, followed closely by the small intestines, propelled by the superior force of the upper muscles. A vacuum cannot certainly exist in the abdominal cavity; and as Mr. Pott justly observes, the moment the equilibrium (of muscular power) is lost, a displacement of some of the viscera takes place. That the intestines are displaced, and closely press upon the falling uterus, is

* Pott's Works, vol. ii.

* Dr. Sterling's translation, vol. ii. p. 259.

averred by Velpeau*, and, if I am not mistaken, by Sir Astley Cooper. As a powerful remote cause of displacement of the pelvic viscera, relaxation of the broad tendinous terminations of the external oblique muscles should not be overlooked. These tendons counteract in a considerable degree against the downward forces of the abdomen, and relaxation in them produces a fulness in the iliac regions which very much favours the descent of the abdominal upon the pelvic viscera.

I have seen several cases of distension of the inguinal regions very marked indeed, connected with dyspepsia, and premonitory of hernia, arising from relaxation of these broad tendons; but more generally in cases of descent of the intestines upon the pelvic viscera, the whole hypogastrium is enlarged, and the umbilical region flattened, and even hollows in accordingly.

I am convinced that more observation will detect this state of the abdomen in prolapsus ani and pelvic hernia, as well as in prolapsus uteri.

These views are ably set forth in a pamphlet addressed to the medical profession explanatory of Dr. Hull's utero-abdominal supporter†.

"In cases of long standing," says Dr. Hull, "the posterior portion of the vagina becomes very much distended, and the whole of the soft parts closing, the lower outlet of the bony pelvis assumes a pouch-like figure; and this unnatural cavity is filled by the (prolapsed) uterus and bladder, *held down by the displaced abdominal viscera*."

If, then, the uterus be considered a passive body, and like most of the abdominal and pelvic viscera, held *in situ* by the equally balanced muscular, tendinous, and bony walls of the great cavity and the correctness of the idea be admitted, that its displacement, at least in its unimpregnated state, is owing to relaxation of either the perineal or hypogastric portions of those walls, or of both—the *rationale* of Hull's external support against these weakened and relaxed portions is quite evident, and the solution of its undeniable success ceases to be a surgical enigma. Dr. Hull's apparatus has many advantages over the pessaries, which render it highly worthy

the attention of the profession. In the first place, if there be scirrhus polypus, slight ulceration of the vagina or os tincæ, it is by no means injurious in its effects, but as I have seen it in each of these cases, proves beneficial; perhaps more so than any and all other treatment: whereas pessaries of every kind are totally inadmissible, however urgent the coincident prolapsus may be, and the patient is necessarily confined to bed incessantly, with but a meagre hope of restitution. This advantage obviously relieves the practitioner of great anxiety in regard to the diagnosis, which in these cases is often painfully difficult, and to me not seldom wholly impracticable, especially in the first eight or nine years of my practice.

2d. The evils produced by pessaries are wholly avoided; viz. the difficulties and unpleasantness of their proper introduction, frequent removal, cleansing, and replacement; and the inflammation and ulceration produced by them*, which are always tormenting, and sometimes fatal.

3d. The perineal wedge and strap of Hull's instrument, by pressing upon the whole median line of the ano-perineal region from the coccyx to the vulva, in an upward and forward direction, close the vagina from without, and tend to strengthen it, while its calibre is diminished; whilst the pessary of every kind distends the vagina, and tends to press it against the rectum and anus, producing many unpleasant sensations, and seldom if ever accompanied by salutary results.

4th. Hull's apparatus can *always* be applied in prolapsus, whereas it not unfrequently happens that inflammation or tenderness of the parts or incipient organic affections, prevents the introduction of pessaries entirely, and the patient is obliged to submit to confinement, strict regimen, and the like, for a very long time, which rarely fails of making lasting and serious inroads in her general health, even if the visceral displacement be removed.

[We understand that Dr. Hull's apparatus may be had of Mr. Higham, 279, Regent Street.—Ed. Gaz.]

* Ut supra, vol. ii, p. 257.

* See Mad. Boivin, Cooper, and many other writers on this subject.

ON UTERINE HÆMORRHAGE.

BY ROBERT HULL, M.R.C.S.

To me it seems that adequate attention is not always paid to the nervous connexion of the womb with the brain; so that complete tranquillity of mind, which should be aimed at by every accoucheur, is not always secured.

To a very great extent, the womb appears independent of what Bichat has termed the *vie animale*, and the growth, conservation, and expulsion of the fœtus, belong apparently to the *vie organique*, as their main and essential origin. I use these unsatisfactory terms, from want of better, in our present ignorance of the nervous system.

This independence of the womb may be collected from such an instance as the following:—

A young villager, of Costessey, near Norwich, about five months pregnant, staid out of doors during the whole night at a fair—one of those saturnalia which still disgrace our country and its legislators. She was speedily attacked with perfect paraplegia, and was utterly unconscious of the hand examining the womb per vaginam; yet she went her full period, and I was informed by Mr. Bond, the parochial surgeon, that she gave birth, unassisted, and easily, to a developed and living child, herself unconscious of its transit into the world. She died of her disorder some short time after. Here, therefore, utero-gestation and parturition were accomplished, independent of the cerebral system—the *vie animale*.

To me it seems that the womb resembles the other organs—thoracic, abdominal, pelvic; independent of the cerebrum, yet easily affected through it. How numerous are the proofs of mental influence displayed upon the heart, the digestive organs, lower bowel, kidneys, bladder!—viscera which act best when they are left to themselves, unaffected by mental commotion. It is, most probably, from this cause that the secretions of the cavities just now mentioned are most duly performed during sleep.

Of all the passions, terror appears to be the most potential. Witness the palpitating heart and hurried respiration, the sick stomach and relaxed bowels, the evacuating bladder—"the natural or universal language of this passion." Now, without disputation

about words, *mihi de vocabulo pugna non est*, common sense assures us that fear acts by relaxation.

Yet relaxation is the very worst state for a parturient womb, especially an empty and unclosed womb. Whilst its muscular apparatus declines to contract, the smaller arteries yield to the *vis à tergo*, and the absorbent extremities of the veins are paralyzed. At this condition resulting from protracted labours, which waste the vital power, we cannot wonder. A furious labour, of hours, of days, of a week (and such has been witnessed), must leave the womb but little contractile energy, and hæmorrhage occurs, the result of simple physical exhaustion.

But it is not difficult to conceive an equal amount of hæmorrhage, and yet the corporeal exhaustion less; the mind, fearful and despondent, producing a relaxation equal to that created through mere physical fatigue.

Nor is it marvellous that any woman should be terrified, when she perceives the consternation of her attendants, and the haggard features of her accoucheur. No wonder that, if she has begun to lose blood, she should now go on to flood.

This is one of many a crisis, when true science may be distinguished from spurious pretensions—from those of the practitioner, whose fame is as false as it is ignoble, founded on a systematic assumption of the merit of every favourable delivery, when the whole process has been performed by the organs of the credulous sufferer.

"Aderat fortuna, etiam ubi artes defuissent."

Accoucheurs of this sort may be found in every populous region; and it is surprising to witness the notoriety acquired, and the monies pocketed by tricksters, whose obstetric knowledge is only anile; who, when nature is at fault, are helpless and aghast; and communicate to their patients their own perilous terrors.

The influence of the cerebrum on the parturient actions, however essentially they may be independent, is well known to all accoucheurs of experience, who almost constantly witness illustrations. The intelligent accoucheur knows that gloomy conversation—narratives of disaster and death—weaken or suspend the most vigorous uterine action. What, therefore, may occur before the birth of

the child, may take place afterwards, when the placenta has been extruded. After a natural expulsion of the after-birth, and a dense conglobation of the womb, mental emotion may abolish the contractile action, and hæmorrhage be the result.

A case of recent occurrence I think illustrates my theory. A lady, whose previous labours had been hæmorrhagic, was seized with a post placental flux, which brought her to extremes. The pulse was imperceptible. A very strong opiate, sixty drops of the liquor sedativus, succeeded by liberal potions of diluted brandy, produced a sleepy state; and, during the snatches of sleep, her pulse became distinct and regular, although it was very rapid. Every time she awoke from these transient naps, her pulse lost its development. This phenomenon I believe to have resulted from mental commotion, in a patient of delicate fibre and sensitive mind. This lady recovered.

And I think I may venture to say that the *post placental* hæmorrhage most usually is the misfortune of patients of this crisis rather than of an opposite. That it occurs less often, and as an exception, in the coarse and careless parturient.

I am informed that uterine hæmorrhage is, comparatively, very rare in the parturition of the lower animals. It is not illogical to infer that this immunity is owing to their comparative freedom from moral influences. I say "comparative," because I cannot hold with the dogmata of those philosophers, who have maintained that the brute animals are simple machines, moved without spontaneity; nor with others, who evade a solution of their mental and moral phenomena, through the use of the term instinct—a mere term, without any satisfactory ideas.

"Manifestum est, non minori tantum cognitionis vi, quam homines pollere, sed rationis prorsus esse expertia, non humana tantum cognitione carere, sed quæcumque aliâ, quæ fingi potest, esse destituta; uno verbo automata esse, et non delectu, sed mero impotu agere." This philosophical tomfoolery will not be easily conceded to Antony Le Grand.

Impressed with the opinion that many cases of *post placental* hæmorrhage depend on mental commotion, I administer, almost always, when the placenta is detached, a powerful opiate, varying in

strength according to my apprehensions, founded on the history of past labours, the sensitive *morale* of the woman, or general circumstances.

I believe that this practice has been satisfactory; that by sending the patient into a cerebral repose, if not sleep, and thus leaving the womb to itself, and its ganglionic energies, I have prevented hæmorrhages, which would otherwise have occurred from the relaxing uterus.

This, however, it is impossible to demonstrate, because the argument is of a negative character; as the relaxation may not have occurred, even without the use of a narcotic. But after a practice of twenty years, a man may arrive at a well-founded belief, although he cannot detail the numerous, varied, and complex phenomena, wherefrom he argues, to the clear comprehension of an auditor. There is a conviction derived from experience, which the rules of the schools cannot impart; nor the language of the schools render intelligible.

When *post placental* hæmorrhage proceeds to influence the heart and arteries, no time should be lost. I have never feared in this distressing and critical condition to administer wine or ardent spirits most liberally. I know that to this proceeding is opposed a horror, in some minds, of "stimulating empty vessels." But this means less than it expresses; and perhaps it means nothing at all, since no living vessels are perfectly empty; they are only less distended: and if vigour and contractile resistance to the *vis à tergo* be given to the extreme vessels, this is the very effect we covet.

The administration of opium seems inconsistent with that of alcohol; and he who has thus prescribed, has been challenged "to reconcile his practice with reason." Yet this is not so very difficult, if we consider that a liberal supply of ardent spirits produces, like opium, a narcotic influence on the brain; the very object of my endeavours in hæmorrhage. But granting even, if any person demand it, that opium may be a stimulus, even on this assumption the benefit of the drug is deducible. The stimulus mainly acts on the cerebral system, and dispels that anxiety which I suppose to exert a paralyzing influence on the muscular fibres of the womb. The loquacity induced by those liberal potions of alcohol,

which Dr. Blundell prescribes, as reported in his published lectures, proves, I think, that anxious terror has been dissipated by them. And if opium only acts in this way, and to this degree, who will despise its agency?

I believe there is no department of medicine which demands from the practitioner a cheerful, encouraging demeanour, so urgently as the obstetric. And, looking round me, I think I can trace their success as accoucheurs, in the case of many famed midwives, to their hilarity and habitual self-possession. On the contrary, I think I have ascertained that a surgeon may be a very intellectual and accomplished person, and yet "unfortunate" as a midwife, from the very gravity engendered by his real science and profound valuation of human life.

In what way the mind affects the womb must remain a mystery, while we continue in the dark as to the nervous power. Since the womb can conduct its expulsive process, although disconnected from the brain, as shewn in the paralytic girl of Costessey, we should incline to discredit any cerebral influence. But the fact is positive. The mind does frequently suspend the contraction of the womb. In these cases, therefore, the power which it subtracts, it may previously have conferred. Perhaps the truth is this, that although the womb is essentially independent, and can, in extraordinary cases, manage for itself, yet in usual, natural instances, it derives from the cerebrum a certain and natural aid.

Nothing, since the discussions on the "excito-motory" system, has, I believe, been elicited to throw light upon this uterine subject; and may heaven prevent any bloody experiments on the lesser animals! My heart sickens at the narratives of these miscreant, murderous philosophers; on whom, if I wielded despotic sway, I would most assuredly perpetrate their own cuts and manglings. What proportionate benefit has resulted from the terrible amount of animal suffering? what frightful agony has been inflicted for no definite object, or for objects just as attainable without zoicide, or not valuable after all?

Discovery, in the medical art, if to be made through the wilful torture of animals, is obtained so deplorably, that a man should anxiously satisfy his con-

science, that he enacts no indefinite, childish mutilations. Mr. Grainger, in his philosophical brochure on the Excito-Motory System, has inflicted a just castigation on one of these reckless men of blood, whose numberless assaults on his majesty's liege beasts, made him, when torturing in England, a subject of parliamentary discussion.

For students of physiology, who, undirected, unsanctioned by their preceptors, dare to mutilate God's creatures—for those incipient practitioners, who covet a small fame, as philosophers, from their admiring relative and lay-friends, by the diabolical mutilation of living dogs, cats, and rabbits—I commend them to the mercies of the magistrate, who surely can punish their brutality under the Act "against cruelty to animals;" a legislative enactment, which confers enduring honour on its generous, brave, and tender-hearted projector, Richard Martin. It is impossible to recal the exertions of that noble fellow without deep regret that his manly philozoical career has long since terminated in the grave. "*Præcipe lugubres cantus, Melpomene!*"

To conclude, I would impress on junior practitioners my own deep conviction, that they cannot attend too much to the mind of their parturient patients, whether to prevent or to restrain hæmorrhage. This catastrophe, always terrific, is at times awful; yet they must resolve to put a good face upon the matter, and, whatever they may feel or fear, they should evince no more emotion than a statue or a quaker.

Whether after the expulsion of its contents hæmorrhage be ascertainable, or previously internal hæmorrhage be only suspected, the man who terrifies his patient by his looks, or tells her, as I have known her told, that she is in danger, so paralyses her uterus—the very part on which all hope depends—that he must, whatever his practice or his fame, be accounted an unphilosophical midwife.

As a physical appeal to the uterine muscle, the accoucheur will find the *secale cornutum* marvellously powerful, whether the *fœtus* and placenta be within or extruded. Indeed, it is sufficient to say that uterine contractions are by the *secale* produced; and the common sense of the midwife will tell him how admirable an agent it must be in hæmorrhages from the womb. I am aware

that an accoucheur of great name continues to despise the ergot, in spite of the mass of favouring evidence. Such incredulity is interesting, and reminds one of a living sceptic, who said to me, "I believe nothing which I hear, and only half what I see."

I attended Mrs. S. at the birth of her eighth, ninth, and tenth children. The detachment of the placenta each time was succeeded by hæmorrhage most alarming; in the last case, awful. In this, when the prostration was urgent, I gave most liberally alcoholic stimulus. Mr. Johnson was summoned to my assistance, and the symptoms, all but fatal, gradually yielded.

Her escape was so narrow that I resolved to try, in any subsequent labour, the preventive influence of the *secale cornutum*. This patient had been delivered in her seven prior accouchements in Yarmouth; and, from her account, each labour had been succeeded by terrifying losses.

At her next parturition, the eleventh, I found the os uteri patulous, the vagina lubricated and yielding, and the pains regular. I directly administered the tincture of ergot, which excited rapidly an energetic pain; and this did not cease until the womb had discharged all its contents. No hæmorrhage whatever occurred, for the first time after so many labours.

In a subsequent labour, in the year 1837, she was treated similarly and successfully.

From numerous cases I can no more doubt of the influence of the ergot to produce uterine contraction than of my own existence; and I have given it with impunity in larger doses, more rapidly repeated, than I have seen prescribed in any work. The tincture, or Bass's concentrated essence, I use for the sake of convenience; but a fresh infusion tells best. Having decided that the case demands this provocative, I look less to the measure and number of the doses than to the influence they exert.

If the junior accoucheur keep in his mind the paramount object—to wit, the contraction of the womb—he will avoid much that is absurd and much that is disgusting. Sitting upon the abdomen of the patient, with or without "the family-bible" interposed, I call absurd, since no such pressure can place in precise contact the walls of the uterine

cavity, and mechanically close the vessels. Thrusting the hand and arm into the womb, and pouring cold water over the naked belly, I call disgusting, barbarous, and to be religiously eschewed if possible.

Norwich, Oct. 31, 1833.

ACUPUNCTURATION IN ASCITES.

To the Editor of the Medical Gazette.

SIR,

If the following case and remarks are worthy of a place in your valuable journal, they are at your disposal.

I am, sir,

Your obedient servant,

JAS. CAMPBELL,

District Surgeon to the Eastern Division of Calton.

12, Millroad Street, Calton,
Glasgow, Oct. 29, 1838.

Eliza Stevenson, residing in Cockburn's Close, aged 30, of middle stature, constitution originally good, but now rather debilitated, came under my care as a pauper patient in December last, labouring under ascites of three weeks' standing. The various remedies that are usually prescribed in ascites were had recourse to, such as squill and supertartrate of potass, squill and calomel. The calomel was pushed until slight ptyalism was produced, yet the disease did not yield. After the ptyalism had gone off, the bowels were well acted on by means of hydragogue cathartics. The disease still made progress; the respiration became very much impeded; the abdomen was distended so enormously that it measured fifty-three inches around the umbilicus. No medicinal agent having been administered for two or three days, I resolved to make trial of acupuncture, which was accordingly done on the 10th February, when upwards of twenty punctures were made with a fine sewing needle $2\frac{1}{2}$ inches long, attached to a handle. The punctures were made generally over the whole anterior part of the abdomen; some were attempted to be made toward the lumbar regions, and failed, on account of the obliqui muscles contracting, carrying the point of the needle in a lateral direction.

11th.—Complains of sharp shooting pains passing through the abdomen, the

skin of which feels tense ; pulse quicker, feverish.

12th.—Immediately after yesterday's visit, says she began to perspire, when the febrile symptoms went off, since which has passed more urine than she has done for these four days past ; abdomen œdematous.

14th.—Continues to improve ; abdomen measures forty-seven inches.

17th.—Abdomen still decreasing.

20th.—Abdomen measures forty-three inches.

23d.—For the past three days the disease has been stationary. Calomel and squill were now ordered, the only medicines given since the operation. I learned afterwards that by the 2d of March she was completely free from her dropsical symptoms, measuring only thirty-six inches ; and up to the present there is no return of the disease.

Remarks. — That acupuncture acted a remedial part in this case, appears evident from the fact, that no medicinal agent had been administered for two days, at least before the operation, nor until thirteen days after it, by which time the abdomen had fallen ten inches ; also, the marked change in the symptoms, commencing the day after the operation, confirms the more. The *modus operandi* of acupuncture is as yet involved in mystery. Mr. King's opinion, whose case is recorded in Nos. 2 and 9, of the first volume of the MEDICAL GAZETTE, for the Session 1837-8 is, that the fluid oozes from the cavity of the peritoneum into the subcutaneous cellular tissue, no mention being made as to whether the absorbents are stimulated to action by the puncturing or not. Dr. Elliotson, in the Cyclopædia of Practical Surgery, article Acupuncture, says, "The effects of acupuncture are not deducible from counter-stimulation, for they are sometimes most remarkable when such stimulation has been scarcely felt." With Mr. King's opinion I perfectly agree, from the tense and œdematous state of the abdominal parietes, the day after the punctures were made ; but with Dr. Elliotson I cannot so readily agree :—the sharp shooting pains, the quick pulse, the heat and fever, experienced by my patient, during the twenty-four hours after the puncturation, can alone, in my mind, be attributable to the counter-stimulating effects of the punc-

tures. Mr. King made few punctures at a time, and repeated these every second or third day : from the results of the present case I should rather be inclined in all cases to puncture freely at first. That it be necessary to repeat the operation I have no doubt ; yea I should deem it advisable toward the termination of the disease, to repeat the operation, for the purpose of establishing a more permanent cure, which I certainly would have done on the 22d, the day the calomel and squill was ordered ; but I was then labouring under the first symptoms of typhus, and it was not until the month of May, that I learned of the successful issue of my case. In performing the operation, the needle was passed quickly, with a rotary motion, rotated freely when introduced, and during the time of extraction, when a drop of fluid appeared at the orifice : no pain was felt except when the needle was attempted to be passed, toward the lumbar region. From the result of Mr. King's case, and that of the present, I certainly would in all cases prefer the operation of acupuncture to that of tapping.

USE OF OIL IN PAINTER'S COLIC.

To the Editor of the Medical Gazette.

SIR,

AN interesting case of colica pictorum has just occurred to me ; I should therefore, be obliged by a corner for it in the MEDICAL GAZETTE.

The subject was 19 years old, stout, an apprentice to a painter. It was his second attack, the first being about a year ago, at Nottingham. He was then attended by several medical men, on account of the severity and obstinacy of the disease.

The most important circumstances in the case were, firstly, the apparent means of recovery ; then the heavy aching pain along the dorsal vertebra, with agonizing tormina in the belly generally ; the dirty ashen colour of the whole surface of the body, the complexion being fair during health ; and the dark tarry consistence of the blood, with a small and slow pulse (56 per minute.)

I shall not trouble you with a detail

of the symptoms; they were those of colica pictonum.

Large quantities of calomel, solid opium, laudanum, castor oil, several bulky clysters (the last containing Sp. Tereb. ζ ii) were given during the twenty-four hours succeeding my first visit, but without much effect on the complaint. Some relief to the pain, however, was derived from a sinapism to the whole abdomen. Very little blood was drawn.

At this time I asked the patient what had done him good on the previous occasion. He said, a quantity of goose grease and yeast; that this procured an evacuation when all other remedies had failed. I immediately ordered him to take about four ounces of the mixture in equal proportions; and a hard motion was the speedy consequence, together with considerable subsidence of the colic. Another dose was given the next day with similar good effect, and he has gradually recovered. He had been ill more than a fortnight without advice.

Moderate salivation was established in forty-eight hours after beginning the use of calomel and opium; but seeing that ease was procured before this period, and that these medicines had, in all probability, been unavailing in the first attack, I attribute the recovery solely to the yeast and melted fat.

My inference from this case is, that olive or castor oil, in large quantities, either or both by mouth and per rectum, should be made more prominent in the treatment of this frightful, but not often fatal, disease. The oils, I understand, are employed largely in Sheffield; but little is said about them in books.

I am, sir,

Your obedient servant,

JOHN J. BIESBY, M.D.

Newark-on-Trent,
Oct. 10th, 1838.

MEDICAL GAZETTE.

Saturday, November 10, 1838.

"Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tuetur; potestas modo veniendi in
publicum sit, dicendi periculum non recuso."

CICERO.

CASES OF MALAPRAXIS.

WE believe that no one in this country has attempted to form a col-

lection of instances of malapraxia, or to shew, by a nice gradation of cases, in what variety of ways a practitioner may be criminal, or blameable, or barely justifiable. Something of this kind has lately been done in Prussia by Dr. C. F. Koch, who, in a very elaborate article in Rust's Magazine, has given and classed a number of cases of malapraxia, confining himself, however, to those which have occurred during ten or twelve years in a single province. It will be interesting to our readers if we select some of Dr. Koch's histories, as they will not merely exemplify the way in which such matters are managed in Prussia, but give a few useful hints for the investigation of similar occurrences in England.

In the following case the accusation was, that Dr. X. had violated his duties as an accoucheur. A midwife was called to the labour of Mrs. D., the wife of a working man, who three years before had been delivered of a stout boy, with the assistance of Dr. X. She found the left thigh of the child, almost as far as the abdomen, already born, but from the weakness of the pains, she wished to have the aid of the accused. He came immediately, but on account of having before been insulted by the husband, and not having received his fee, though he had often asked for it, he refused to deliver the woman, and sent the midwife to the burgomaster, for an order to be paid out of the town-chest. The midwife returned, not having succeeded in her commission, and found him gone. In about three-quarters of an hour stronger pains came on, and the midwife succeeded in bringing a dead child into the world. A quarter of an hour previously the child was alive, according to her statement; for when it was born as far as the shoulders, she laid her hand upon its chest, and felt the heart beating. The head could not get disentangled until a quarter of an hour

later, after the arms were freed. The mother had felt the motion of the child, though not strongly, until a short time before the commencement of delivery.

The question proposed by the Criminal Court to the Medical College was, "If proper assistance had been given, *might* the child have been brought into the world alive?" This was answered in the affirmative, because the child was alive till the time of birth, because there was no prolapsus of the funis, and because the child's head had been delayed a quarter of an hour in the smaller aperture of the pelvis; now this dangerous period could not be shortened by the midwife, but might have been by the forceps of the accoucheur. They added, however, that the saving of the child's life by judicious artificial assistance must, at the utmost, be considered merely as probable.

The sentence of the tribunal of the first instance was based on the supposition that a physician is not, as such, an official personage, but without being a public officer, is *only* especially devoted to the public weal; by which it seems to be intended, that though obliged to serve the public, he is not quite so much obliged as if he held an official station. They added that there were no special punishments assigned for the wilful neglect of the duties of an accoucheur, whence it appeared that when no damage arose through his neglect, the accoucheur is not punishable; yet that the accused would have been liable to an imprisonment of a year's duration, had it been made out that the death of the child was caused by his gross neglect; but under existing circumstances he was merely condemned to a fine of 100 dollars (16*l.*)

The tribunal of the second instance mitigated the fine to 20 dollars (3*l.* 4*s.*),

and laid it down that a physician is unquestionably an official personage, and that the accused was guilty of gross negligence in his vocation. The legal punishment was, in consequence, a fine, which, from the extenuating circumstances, the former insults of the husband, and the numerous testimonials in Dr. X.'s favour, was mitigated to twenty dollars.

A curious point in this judgment is, that the higher tribunal diminishes the fine, although by declaring the accused to be by his profession an official person, it seems to exact more from him than the inferior court. The illegality of the accoucheur's conduct consisted, we suppose, in going to the labour, and then refusing to do any thing; for we presume that he might have declined attending the case altogether. And yet, perhaps, his title of official personage might imply that he must necessarily attend when summoned by a midwife. It is clear that the half-educated midwives of Prussia, and other continental states, are a great blot in their medical arrangements. To entrust the majority of labours to women so ignorant that they are obliged by law, as well as by their own incapacity, to call in assistance in almost every difficulty, seems a very awkward way of doing business. The general poverty of the inhabitants, and a preference given to women may, of course, partly account for it; yet one would imagine that in the well-drilled population of Prussia it would be easy to force such a quantum of education upon the midwives as would render them adequate to struggle with all the ordinary emergencies of their profession.

The next accusation is against one of these unfortunate *sages-femmes*, whom the law supposes not to be very sage.

Mrs. Z., aged twenty-three, was safely delivered of her first child, but

the placenta did not come away. The accused says she told the woman to be patient, and not to bear down. Mrs. Z. suddenly called the midwife away from washing the child, exclaiming, "It's all coming out down here", and on going up to her, the midwife found the placenta, together with the uterus, protruding beyond the external parts. She dipped her finger in oil, entirely detached the placenta, and endeavoured, but in vain, to replace the uterus, which was of the shape of a small head. In three quarters of an hour the woman died; but she had not lost much blood, according to the midwife: there was only a small quantity under the straw bed. The mother of the deceased, however, contradicted these assertions, and deposed, that the midwife, after the birth of the child, had told the woman to bear down when a pain came on. Moreover, she had got into the bed, and squatted (*niedergekauert*) between the extended thighs of the woman, and had repeatedly worked with her hands in the genitals of the witness's daughter, though an apron which she spread over prevented more accurate observation. When the uterus prolapsed, the accused cried out, "What is that—that's not a child—I don't know at all what it is"! Her daughter grew pale, and there was a great gush of blood: the protruded uterus was double the size of a man's fist.

Several hours afterwards Dr. R. came, who recognised it to be a case of inversion of the uterus, and felt persuaded that the woman had bled to death. Remnants of the placenta, fresh in appearance, and of the size of a cherry, were adhering to the inverted uterus, which was easily replaced. The body was not opened, but its aspect sufficiently shewed the entire deficiency of blood.

The College gave it as their opinion, that although not proved, it was in a

certain degree probable, that the accused, either directly by violent pulling at the funis, or indirectly by inciting the woman to bear down, had caused the inversion of the uterus, especially as it did not take place till a considerable time after the birth of the child. But at any rate she acted contrary to rule, in separating the placenta from the uterus, even if it were already partially detached. The accused, too, did not shew the necessary presence of mind and skill by quickly replacing the uterus—an operation which it was requisite to perform instantly; nay, it is doubtful if she recognised the condition of the deceased. She confessedly very soon desisted from her attempts at replacement, and set about making warm milk poultices.

They observe, in conclusion, that although inversion of the uterus is always a most dangerous occurrence in labours, yet it is not proved that the accused caused the death of the woman by her mistakes alone, as the cause of the inversion remains doubtful.

We are surprised that the midwife is not blamed for having neglected to call in better advice at an earlier period, as there appears no reason to suppose her capable of managing so alarming a case without assistance.

The last case which we shall give is one in which a surgeon was accused of ignorance and neglect:—

A tailor, named S—, deposed that his wife, aged 45, had an easy and safe delivery on the 7th of October, and went on well for ten days afterwards. After considerable vexation she complained towards the evening of violent shivering and headache; and in the night there came on heat and pain in the right side of the abdomen. Next day the pain extended to the right shoulder, with great heat and loss of appetite. On the twelfth the advice of

the accused was asked. He prescribed a grain and a half of opium, and half a drachm of rhubarb, to be taken at twice within two hours; and an ounce and a half of Glauber's salt, to be taken dissolved in eight ounces of water. After these remedies the patient lost the pain, but felt as if her heart would make its way out. She complained of want of air, and of pain in inspiration. The laxative was continued, with the effect of sinking the spirits of the patient. Nevertheless, the next day the accused continued the medicine, and on the fifteenth day the disease seemed to diminish. The accused now prescribed nitre and camphor in solution; but after half the mixture had been taken, the sense of anxiety about the chest increased, and the patient died towards evening.

The Board, in giving their opinion, thought it might be assumed with great probability that Mrs. S—— was labouring under inflammation of the liver, and inferred from this supposition that the treatment was not only not suitable, but mischievous. Moreover, the accused was censured for his want of attention in ordering the powerful remedies first prescribed, without a personal examination of the patient, whom he did not visit till three days had elapsed, during which her condition grew worse.

Nothing is said in this opinion about his having overstepped his privileges (by prescribing in a medical case, we suppose), though this is one of the items of accusation in the heading of the narrative.

We must reserve our commentary upon this case for another occasion, when we shall also give some more of Dr. Koch's instructive histories.

ENDERMIC MEDICINE.

THIS method of administering drugs may be considered as quite recent; for though some hints on the subject are to be found in the writings of the Greek physicians, it can hardly be said to have been practically adopted until about ten years ago, when Bally published the result of his experiments. According to him, medicines are more powerful when applied as near as possible to the origin of nerves, and upon a great number of small surfaces, than if placed upon a single large one. Injurious effects are counteracted by removing the drug and applying a cupping glass to the exposed surface. He chiefly experimented with narcotics, and thought that the effects were clearer than when they were administered internally. Lesieur tried several remedies, and found that the choice of the spot was a matter of indifference.

SECT. 1.—METHOD OF APPLYING THE REMEDIES.

Removal of the epidermis.—The cuticle must be destroyed, in order to reach the rete mucosum, where the skin has the power of assimilating. For this purpose, Bally, Lesieur, and Lembert, employed blisters; but to produce the effect more rapidly, Lesieur recommended the use of cotton dipped in sulphuric acid, of hot water, ammonia, or strong acetic acid; or grazing the part with the bistouri. Lembert always preferred blisters. Hoffman introduced the drugs into leech-bites, or incisions in the skin—a method which he afterwards gave up. At a later period he preferred dipping a knife or a knitting-needle into boiling water, and then pressing it against the skin so as to cause excoriation. The spots for introducing the drugs were to be frequently changed. Dr. Richter rubs the spot with a solution of caustic ammonia, and places a blister over it; and, after applying the drug, puts on a bandage with a suitable ointment.

Number of spots.—A single spot, provided it is relatively large, is usually sufficient. Bally, however, recommends several small ones, and so does Trousseau in rheumatic affections.

Choice of the part.—A spot is to be chosen, where the cuticle is easily destroyed, and where absorption is the strongest, at the same time that it is as near as possible to the seat of disease. In nervous maladies the neighbourhood of the central organs is to be preferred; but if in nervous maladies, a more local effect is intended, a spot more remote from the central organs must be selected; this holds good especially of narcotics.

Time of continuing the application.—In general, the effect soon shows itself; and therefore on account of the secondary effect of remedies, this method must not be continued long. It is only when the result of the first trial is advantageous that it may be repeated.

Form of the remedies.—The vegetable alkaloids, particularly the soluble ones, are the most efficacious endermic medicines, and these are best applied in the form of powder. When the doses are small or difficult of solution, it is well to add a little sugar, and to dissolve the whole upon the exposed spot with a drop of water. Dr. Richter previously dissolves resins in a little spirit, and then puts them on a bit of linen spread with simple ointment. Very irritating substances are advantageously enclosed in a mass of plaster, or placed between folds of thin linen or gauze.

Dose of the remedies.—The more soluble the substance is, the smaller must be the dose to begin with; and this is especially true of narcotics. With them the commencing dose should be only one-eighth, or, at most, a quarter of a grain; and less, if the patient is a child, or if the medicine is applied in the neighbourhood of the brain or spinal marrow. With other remedies, which do not act directly upon the centre of the nervous system, we may be bolder, and particularly if they are not easily soluble. Whether they are to be repeated, depends on the effect and the disease.

Effect of the remedies.—This is divided into the local and the general. The first is the result of the irritation of the spot in the skin by the remedy, and appears to be more or less inflammatory, and even caustic. It is necessary that this irritation should be moderate, that the power of absorption may remain; a more violent degree is mitigated by warm poultices. The general effect has hitherto been observed only in the case of narcotics. When other remedies are administered, no particular effect appears in systems or organs, or only a specific one, shown by the direct removal of the disease, as from quinine in ague. Narcotics act quicker through the skin than through the stomach, but do not affect the central parts of the nervous system so soon. They do not act upon the vascular system until narcosis has been produced. No other remedies show their effects until after a longer application. When remedies are applied to the skin, the intermediate agents in producing the effects are the superficial nerves and the absorbent vessels.

Application of the remedies.—The endermic method is most efficacious in cases where the passage to the stomach or the intes-

tines is obstructed, or where, from diseases of these parts, remedies cannot be administered internally; and also when we wish to avoid secondary effects, such as excitement of the vascular system. As narcotics have hitherto shown the greatest activity, the method is particularly applicable in purely dynamic and idiopathic pains, which have no material foundation, (especially in the central organs); but have their seat in the superficial nerves. Nevertheless, time must not be trifled away in this manner, if there is a more certain mode of cure, otherwise we should not only be guilty of a fault of omission, but should injure the patient directly.

SECT. II.—EFFECT AND APPLICATION OF THE SEVERAL REMEDIES HITHERTO INTRODUCED BY THE SKIN.

Morphia.—The primary soothing effect of morphia (which takes place more rapidly when applied externally than when administered by the mouth) is not caused by absorption through the skin, but by a continuation of the excitement of the superficial nerves, influenced, however, by the vicinity of the spot to the affected part. If the application is long continued, it passes through the absorbent vessels into the mass of fluids, and thus by its secondary effect on the vascular system, produces a narcosis which lasts longer than when it is swallowed. This may be explained, if we consider that when morphia is introduced into the stomach, nature makes an attempt in the vascular system to counteract the poison, and thus the storm in the nervous system is quelled; whereas, this is the seat of the poisonous excitement when the drug is applied through the skin. As it is uncertain how great may be the sensibility to this remedy, it is advisable, particularly if it is introduced near the central organs of the nervous system, to begin with small doses, such as from $\frac{1}{4}$ th to $\frac{1}{2}$ th of a grain a day. Its effects must be observed, and the quantity gradually increased; but the application must be discontinued as soon as headache or giddiness comes on.

Acetate of morphia.—This preparation has been preferred on account of its solubility, and the mildness of its effects; and when properly combined and rubbed in, it has shewn its powers, even though the cuticle had not been removed. It has been particularly used—1. In trismus and tetanus, especially when caused by external injuries, or by mental affections, in which cases it has been used by Lambert, Cerioli, and Romberg. 2. In spasms without a material cause. 3. In poisoning by strychnia. 4. In diseases of the

respiratory organs, namely, chronic catarrh, chronic bronchitis, and phthisis, by Lembert, Lesieur, G. H. Richter, and Romberg.

Dr. Richter found it most efficacious, when all inflammatory irritation had been removed, in pulmonary catarrh, inflammation of the larynx, trachea, bronchi, or pleura, and even in pneumonia, at the end of the second stage, when the secretion in the respiratory passages had abated, and the patient was tormented by a spasmodic cough. 5. In whooping-cough. Here, in general, the results have not been favourable. Berndt, who used it most frequently in this disease, found it had no effect unless when pushed till it began to produce narcotism. Dr. Richter has not applied it, but says it is to be introduced in the cervical region, as Romberg has proposed. 6. In rheumatism. Here it has been advantageous, when there was neither fever, inflammation, complications, material causes, nor dyscrasia present; for in such cases a previous suitable treatment is required. It was of particular efficacy in fixed rheumatism, without either fever, or gastric complication, in rheumatic spasm, or tooth-ache, in fixed pleuritic pains, lumbago, and ischias. 7. In neuralgiæ. When they are not caused by inflammation or material irritation, but are purely nervous affections, they offer an extensive field to the endermic application of this drug. 8. Dysuria, when purely spasmodic, has been successfully treated with it. Dr. Richter intends in future to use camphor, either alone, or combined with morphia. 9. In vomiting, it has been advantageously employed when there was spasm and increased irritability of the stomach and intestinal canal; in scirrhus of the pylorus, its external application as a palliative was more beneficial than its internal use. 10. In delirium tremens. Here the advantages resulting from its employment, as witnessed by Gerhard, would incline one to use it in the cases in which the internal use of opium is indicated. 11. In dysentery. It was advantageously employed by Gouzée, and Dr. Richter advises it in the second stage. 12. In cholera, Hüenthal, of Riga, has seen it quiet the vomiting better than when administered internally. 13. In cancer of the uterus it acted as a palliative, according to Lembert. 14. In intermittent fever it is recommended by Dr. Richter, in those cases only where the disease appears as a purely nervous affection.

Sulphate of morphia.—Hofmann and Gerhard prefer this preparation to the acetate, on account of its greater solubility. The former used it in periodic ophthalmia, hysteric attacks, chronic rheumatism of

the joints, whooping-cough, spasmodic cough, and cancer of the uterus; but his results shew that far from being better than the acetate, it is inferior to it.

Hydrochlorate of morphia.—Trousseau and Bonnet, in consequence of the favourable results of their trials in rheumatism, give the preference to this salt of morphia, like the former one, on account of its greater solubility.

Effect of opium applied to the skin.—Dr. Richter supposes that when the endermic method is employed with children, opium may be better than the preparations of morphia. By combining opium with quinine in this way, he cured an obstinate intermittent neurosis.

Strychnia.—Pure strychnia, and its nitrate, sulphate, and acetate, have been used, and seem to have been employed promiscuously. They first acted as stimuli to the nerves of motion, then on the sensorium, and lastly on the vascular system. The effect was not so violent as when swallowed; yet, according to G. H. Richter's experiments, they require the greatest caution. The commencing dose is to be from one-eighth to one-sixth of a grain daily, which is to be discontinued as soon as twitchings, or even headache and giddiness come on; and acetate of morphia is always to be at hand, being the strongest antidote. Strychnia and its preparations must never be used with children. Dr. Richter found the extract of nux vomica uniformly advantageous in paralysis of the extremities, when it had come on after taking cold severely, without the existence of organic disease of the brain or spinal marrow, and particularly in what is called spasmodic paralysis; and so did Bally, Lembert, and G. H. Richter, when the paralysis arose from poisoning by lead. In G. H. Richter's practice, too, it cured a case of paralysis of the vocal organs, produced in a hysterical woman by taking cold. It was also efficacious in paralysis of one half of the face, in idiopathic amaurosis, and in neuralgia; but in St. Vitus's dance it was powerless. On the whole, it is useful only in purely dynamic nervous diseases, when sensibility and irritability are lessened. Dr. Richter suggests the endermic administration of brucia.

Extract of belladonna.—Dr. Richter has found this useful in spasmodic affections of the thoracic organs, and of the stomach, in which he applied a solution of a scruple of the extract of belladonna in two drachms of cherry-laurel water, with a hair-pencil. He recommends it in the catarrhal affections of very irritable persons—in the second stage of inflammatory catarrh of the chest—in inflammation of

the pleura, the lungs, the bronchi, the trachea, and the larynx—in paroxysmal or purely spasmodic cough—and in neuralgia.

Saffron.—There is one favourable instance of its employment recorded by Lembert, but as substitutes for it are easily found, Dr. Richter has not tried it; nor has he made use of musk or assafoetida. More favourable results may be expected from daturia, aconitina, hyoseyamina, lactucina, delphinia, solanine, brucia, and veratria. The last has been rubbed on the sound skin in the form of ointment.

Stramonium has been found very useful by Recamier and Trousseau in obstinate neuralgia. It is not so apt to excite nausea and vomiting as the acetate of morphia.

Quinine.—The sulphate and acetate of quinine have been employed; they were not inactive, but seemed to have no tonic effect, nor, indeed, any other one, until the intermittent disease ceased through their agency. Topically, quinine acts almost like a caustic. It has been used chiefly in intermittent fever, particularly by Berndt, and its favourable results have been obtained more especially in children. Dr. Richter recommends its use where great irritability of the stomach, idiosyncrasy in respect to internal remedies, diseases of the organs of deglutition, or inflammation of important organs, forbid its employment internally; as also in children, on account of its bad taste. Other observers give the dose as being from three to eight grains, but Dr. Richter says only one. This remedy has also proved beneficial in different kinds of pain of the face.

Salicine is a very uncertain remedy in ague, and *piperine* may be equally dispensed with.

Aloes.—Lembert, Gerhard, Romberg, Monro, Hofmann, Natorp, Wiesbach, and Magnus, alledge that this remedy acts endermically as a purgative; but their authority is not confirmed by Dr. Richter.

Jalapine was applied in doses up to twelve grains, but without effect.

Gamboge.—Gerhard asserts that he has seen good effects from this remedy, both alone and in combination with aloes; while Dr. Richter has not seen any effect from either.

Croton oil, whether rubbed upon the abdomen or applied to the exposed cutis, was most uncertain in its effects, and should not be used endermically, from its being apt to cause erysipelatous inflammation. Neither rhubarb, extract of colocynth, nor claterium, produced purging.

Calomel is said, by Bally, to have been useful in yellow fever and syphilis; and

Lembert, Gerhard, Jahn, and Romberg, bear witness to its effects; yet, according to Dr. Richter, it is inactive. He proposes the trial of the black oxide of mercury and the weaker mercurial ointment, as being more easily absorbed.

Iodine has been tried by Gerhard and Coster, and, according to the latter, is useful in dropsy. Dr. Richter would have it used only where its internal action upon the stomach, &c. is to be avoided.

Oxide of zinc.—Dr. Richter says that Hofmann's experiments on the antispasmodic powers of this preparation must be considered as simply negative.

Kermes mineral.—Dr. Richter has sometimes seen this remedy produce expectoration, but never either vomiting or increase of perspiration—effects which occurred in the experiments of Lembert and G. H. Richter.

Tartar emetic.—Dr. Richter could not perceive the purging and diaphoretic effects attributed to it by Lembert, nor the emetic power observed by Gendrin.

Emetine.—Gerhard alledges that he found the impure preparation* very active, but Dr. Richter's experiments did not confirm this.

Squill.—The diuretic effect of this remedy seems to come on when it has been continued for several days in a proper dose; but the irritation and pain which it causes are adverse to its continued administration.

Digitalis more frequently acted as a diuretic; but, like squill, it was soon necessary to discontinue its use, on account of its irritating effects. Perhaps it may be of some benefit in organic diseases; and *digitaline* also deserves to be employed as a diuretic in dropsy.—From a review of Dr. A. L. Richter's work, entitled, "*Die endermische Methode*," in *Schmidt's Jahrbücher* June 9, 1838.

WESTMINSTER MEDICAL SOCIETY.

November 3, 1838.

DR. CHOWNE, PRÆSES, IN THE CHAIR.

Fatal Monstrosities.—Mr. Thomson on *Hyper trophy of the Mamme*.

THE chair was not occupied till late in the evening. A gentleman, whose name we could not catch, commenced the business of the evening by relating a case in

* This is otherwise called coloured emetine; the pure preparation being white.—TRANSLATOR.

which a mother was frightened during pregnancy on seeing a dead cat floating in a tub of water. She went her full period of utero-gestation; but when confined, the infant's features presented a strong likeness to the feline countenance. Several other gentlemen enumerated instances of monstrosity occurring after incidents which the mothers recollected perfectly, and which instances and incidents petticoat physiologists had always united as cause and effect.

Mr. Clarke related a case in which the mother was alarmed at the sight of an elephant in the Zoological Gardens, and the infant had afterwards several elephantine qualities; and also another case where a mouse was the cause of the fright, and the child was subsequently remarkable for a predilection for cheese.

After a great many such interesting nursery stories had been told, Dr. James Johnson observed, that all these cases had one remarkable circumstance in common, viz. that the causes were never heard of till after the birth of the child. It was but natural for a mother having a deformed or unnatural infant to seek a cause for the defect extraneous from herself, and her imagination and memory generally found little difficulty in discovering some event during the nine months which could be plausibly elevated to the dignity of a cause. He had heard of mothers being terrified by men with wooden legs, but he had known no instances where the children were born with such appendages.

Mr. Gill stated that he had always been a sceptic as to any influence which the imagination of the mother might have in modifying or arresting the development of the fœtus, till he met with an instance many years ago which staggered him. This was the case of a lady who was very much alarmed by a dream, in which she fancied she had given birth to a monkey. She was six months gone, the idea preyed upon her mind, and at the full period she was brought to bed of a child who had very much the appearance of a monkey. His features had a very *simian* aspect. The metacarpal bones and phalanges were very long; the joints were uncommonly flexible; and he had great prehensile power in the feet. His mental attributes corresponded to his corporeal ones; he was, as he grew up, perpetually in mischief; he would not be educated, and could never learn the difference between *meum* and *tuum*. He was finally guilty of felony, and transported to Botany Bay.

Mr. Chinnock once saw a malformed fœtus in which the head, thorax, and ab-

domen, were deficient; but the pelvis and lower extremities were well formed. The mother, he should say, was frightened by a Bow-Street runner, who arrested her husband. After the discharge of a great many facetiæ by the scientific characters present, Mr. Hall Thomson was allowed to read a paper on *irritable breasts*, which he had announced on the previous evening.

Mr. Thomson stated that his attention had been drawn to the subject of irritable mamma by a case which he had under his care at the Westminster Hospital. The disease had for a long while resisted every mode of treatment that could be devised, but had finally succumbed to a very simple remedy. He would read the history of the case, which was substantially as follows:—

Elizabeth Hobson, a lady's maid, about 16 years of age, was admitted into the Westminster Hospital on the 29th August, 1837, having the right breast enlarged, and very painful to the touch. She had suffered a month before she applied for advice; the pain and swelling had occurred suddenly. She was a tall, exquisitely handsome girl, and more mature than girls of her age usually are; she was of a pale but clear complexion; her face was so perfectly regular, and her figure so truly symmetrical, that her beauty might satisfy the imagination of a Titian. She menstruated as early as her eleventh year, and the catamenia had been perfectly regular ever since. When seen by Mr. Thomson, the left breast was larger than natural, and flabby: her temperament might be considered as belonging to the leucophlegmatic class. The affected breast, on admission, was not remarkably enlarged, but the glands in the axilla were tumid. She complained of acute pain running up the neck of the same side, and shrunk from every attempt at touching the part. Her appetite was indifferent, and she perspired profusely upon the least exertion. Iodine in all its forms, both locally and internally, was first tried without effect. The pain grew worse, and the breast increased in size. Leeches were now applied every alternate morning, with anodyne fomentations, but no benefit accrued. A plaster of opium and strong mercurial ointment was placed over the surface of the mamma, and a sixth of a grain of extract of belladonna given in the form of pill three times a day; cubebæ also was administered. These remedies being useless, all the formulæ of iron were resorted to. Pursuant to the suggestion of one of the physicians, a draught containing half a drachm of tincture of cantharides, and an equal quantity of spirit of turpentine, was administered thrice a day. After these,

extract of belladonna as a cataplasm, hyoscyanus, hydrocyanic acid as a lotion, extract of conium, morphia internally and externally, and two issues made with the potassa fusa and soft soap, were all successively employed in vain. The breast gradually increased in size, and became more and more painful. After six months' treatment she returned home, having experienced no relief whatsoever. She then applied to two private surgeons, who proved equally unsuccessful with the public ones.

After a whole year's suffering, she was again admitted into the Westminster Hospital, on the 28th August ult. She was now somewhat emaciated: her face was haggard, and expressive of anguish; her appetite was null, and her strength had gone. The right breast was three times as large as the other, and excessively sensitive all over its surface. A change of structure was perceptible in the mamma; it was large and unresisting. A large issue was now made on the inner side of the deltoid. The tincture of lytta was tried once more, and the muriate of morphia exhibited every night, but no result produced; then the infusion of gentian with carbonate of soda; afterwards, extract of belladonna; lastly, carbonate of iron, in large doses, but not the slightest benefit was obtained.

At this time a consultation was held by all the medical men of the establishment, and it was resolved that a seton should be passed down to the gland itself, and all medicine abstained from. Even the morphia was discontinued. Two days after the introduction of the seton, the pain in the breast had diminished, and as soon as suppuration was established, the girl gradually improved day by day. In a fortnight the breast was very little larger than the other, and the pain had totally ceased. Her countenance had lost its painful expression. She is now cheerful, has a good appetite, sleeps soundly, and says she feels as well as ever she did in her life. The glands in the axilla are scarcely to be felt.

Mr. Thomson stated that he did not mean to recommend the seton in all cases of irritable breast, for he had met with instances in which setons had been found injurious; it appeared to him that by a careful study of these cases, *criteria* might be discovered that would lead to a careful classification of them in regard to the remedies that should be selected.

Dr. Johnson inquired whether there was any remission or intermission in the pains. It appeared to him that the case related by Mr. Thomson was a well marked in-

stance of hypertrophy of the breast, combined with neuralgia, and it was such a case as would always be relieved by setting up suppuration by means of a seton.

Mr. Thomson stated there was no periodicity in the pains. Mr. Streeter said he had known two instances, in which menstruation had commenced at the age of nine years; but in these there was no complete development of the adult characteristics. He thought it might be considered a rule that precocious menstruation was attended by an imperfect development of some of the sexual organs.

Dr. Chowne thought that in precocious cases the ovaries were always fully developed, though the uterus might not.

Mr. Thomson said that Dobson was in all respects a perfectly formed woman. She had no disease, but the local one he had described.

A gentleman from St. George's Hospital had seen in that institution a case of simple hypertrophy of both mammae, without neuralgia, which had been removed in two months by the employment of the liquor potassæ, in full doses. The use of this remedy had not produced any general emaciation.

Mr. Chinnock mentioned the case of an eminent actress, whose breast had been hurt by Mr. Macready, in one of his tragic efforts. She had been relieved perfectly by an issue in the arm.

Mr. Thomson, in answer to a question from the chair, said, that this woman's bowels had been kept regular. A long discussion now ensued as to the validity of the principle suggested by Mr. Streeter, that precocious menstruation was attended with imperfect development, and the general impression of the meeting was, that this peculiarity was accompanied almost without an exception with a precocious development of the sexual organs.

A gentleman stated, in conversation, that Hobson, whilst in the hospital, had been subjected by Dr. Edward Harison to the mesmeric process. The Doctor manipulated in the orthodox way, recommended by Baron Dupotet, and said he was determined to send her to sleep; but after various attempts on several days he totally failed. The girl said that it produced giddiness, and a little nausea. It was said that this patient was very intelligent; and the circumstance of her thus successfully resisting the would-be magician, proves that she had not only good sense, but honesty.

The president having announced that the clock had told ten, the meeting adjourned.

1810s.

WESTMINSTER HOSPITAL.

Exfoliation of the Bones of the Cranium.

JAMES RYAN, æt. 32, a native of Tipperary, admitted under the care of Mr. Lynn, and suffering from the sequela of syphilis. At the age of 18 he enlisted into the 10th regiment of foot, and was sent out to Corfu, where he became the subject of *lues*. He reported himself to the surgeon, and having been mercurialized to the extent of producing ptyalism, he got apparently well, and returned to duty. He remained free from symptoms during four years. After this lapse of time, he perceived a swelling upon the point of his nose; this continued for six months, when ulceration took place. The oxymercurate of mercury was now exhibited, and ptyalism was consequently produced. The ulceration was healed, and the man again discharged as cured. Having been a month on duty, the swelling returned; the ulceration became worse than ever, and he was kept under the influence of mercury for fourteen months, after which the ulceration ceased, but severe pains in the nasal bones occurring, the mercurial treatment was resumed, the septum narium sloughed, the turbinated bones and nasal portions of the superior maxillary bones exfoliated, and the bridge of the nose sunk. Three years ago he was discharged unfit for service, and was sent home to England. Since his discharge he has had severe aches in the arms, legs, and head, unfitting him for every kind of work. About a year after his return to England, an inflammatory tumor made its appearance upon the upper part of the scalp. This was opened, and a copious purulent discharge flowed from it. The wound ulcerated, and the mischief extended on all sides; and upon his admission into the hospital on the 30th of July, an extensive caries of the cranium was discovered.

Aug. 15th.—Since his admission he has had good diet, he has taken large doses of sarsaparilla daily, and doses of pure iodine, combined with the hydriodate of potassa, in distilled water. The dead bone is now well defined, but firmly fixed. There is a copious discharge of pretty good pus, and the edges of the ulcer are inverted.

25th.—The carious bone is much loosened from its attachment, and is of a dark, almost black colour; its width is about two inches, and its length three. Mr. Lynn made a crucial incision in the integuments, which he raised upward from the bone, and with a strong pair of forceps extracted the dead lamina. This consisted of both tables, and included a portion of each parietal bone, as was evident

from the sagittal suture. The dura mater underneath presented a granulatory surface, and the pulsation of the brain was distinctly visible; a small artery of the scalp was divided by Mr. Lynn, in the preparatory incision, but occasioned no inconvenience.

28th.—Two small pieces of bone have come away whilst he was dressing the wound yesterday. These are like the larger exfoliation, very porous throughout, and jagged at their edges. He had good health until he entered the army; but since he was first affected with syphilis he has been ailing, and he has now large nodes upon both shins. He has had no lichenous eruption on the skin, nor has he had any other sore throat than a common quinsy.

Sept. 7th.—Mr. Lynn has continued, without interruption, the line of treatment already described, as regards both diet and medicine. The patient's general health has very much improved, the rheumatic pains have already entirely disappeared, and the ulceration in the scalp has taken a very healthy appearance.

28th.—The patient has grown stout, his pains have ceased altogether, the ulcer is rapidly contracting and cicatrizing, but there has no disposition of bone taken place in the chasm of the calvarium.

Oct. 10th.—The patient is quite well in health, the wound in the scalp is nearly closed, but there is no restitution of bone. His appetite and strength are perfectly restored. He is consequently made an out-patient. The pulsation of the brain is still observable through the scalp.

SINGULAR INQUEST.

To the Editor of the Medical Gazette.

SIR,

PERHAPS the following statement of an inquest, held sixty hours after death, may be interesting to your numerous readers; if so, it is very much at your service.

I am, sir,
Your obedient servant,
F. FOWKES.

1, Berkeley Square,
Nov. 7, 1838.

Early on the morning of the 17th October last I was called up to see Edward Farrar, a "helper" in the Russian Ambassador's stables, who I was told was very ill, but on my arrival I found him quite dead. It appeared he had not been well for some time, complaining of shortness of breath, for which he had been attended by a shoemaker of the name of Lincoln, who had sent him a mixture and powders, the former apparently containing Spt. Æth.

Nit.; the latter, Antim. Oxysulph. and Calomel. I was not summoned to attend the inquest, but was asked if I would be good enough not to leave home, in case my evidence should be required. On my being called, I found the jury anything but a "respectable" one. Two were servants out of place, another was a servant who lived in the neighbourhood, and another a person belonging to the work-house; in fact, any idlers who happened to be in the public house when the inquest was held, were sworn in as jurors to make up a sufficient number. Of course, Lincoln was too wise to make his appearance, but he sent some of his friends "to watch the proceedings." One, I think, had the good fortune to become one of the jury; another spoke when he thought he could benefit his *friend*, for which he was gently reprimanded. The coroner, too, seemed anxious to get him out of the scrape, and told the jury that it was not contrary to law for an unqualified person to prescribe medicine. This was quite unnecessary, for the jury were sufficiently friendly to quacks; and, after a short consultation, in which doctors were abused for their ignorance of their profession, they agreed to a verdict of "Died by the visitation of God."

LECTURES ON SURGERY,

DELIVERED AT ST. THOMAS'S
HOSPITAL,

BY THE LATE MR. CLINE;

With Notes.

[THESE lectures were written by Dr. Wilkinson when attending Mr. Cline's lectures, in the years 1787-88-89.

Extract of a letter from Dr. Wilkinson, dated Feb. 6, 1838:—"They (these lectures) are the results of six courses of lectures I attended at St. Thomas's, in 1787, 1788, and 1789; and I am in hopes I did not omit any interesting part of Mr. Cline's valuable observations. The one I had the pleasure of giving you is the repeatedly corrected copy."

LECTURE VIII.

Lithotomy.—Causes of Urinary Calculi.—Sounding.—Different Modes of operating for Stone.—Various Instruments employed.—Operation on Women.

Lithotomy, &c.—Calculi are found in various parts of the body; sometimes in the ducts of the *salivary glands*, sometimes in the *pancreatic duct*, very often in the *gall bladder* and *biliary ducts*, and more particularly throughout the whole *urinary canal*. Wherever there is mucus secreted on an internal surface, calculi seem occasionally to be formed, and in that mucus to be occasionally collected, particle by particle, till it forms a large solid substance: this happens not unfrequently in the alimentary canal, more especially in horses, where the formation of calculi is very frequent. I have one taken from the stomach of a horse: its nucleus was a large

crooked nail. The nuclei are different—very various—sometimes a bit of straw. We find not unfrequently a calculus in the alimentary canal, the middle of which is a ball of hair, as in calves, probably from licking themselves when they are shedding their coat. These calculi in the alimentary canal of horses are sometimes of an extraordinary size. We shall confine ourselves at present to those situated in the urinary canal, which are frequently met with in the kidneys, sometimes in the tubuli urinarii, and within the pelvis and its processes; in the infundibulum very frequently. Sometimes calculi are formed in this part of such size as to fill up the pelvis and infundibulum; hence a calculus taken out of the kidney sometimes corresponds with the form of the part. Calculi found within the kidney are often black on the outer surface. I believe, from the irritation they produce, some degree of inflammation takes place, and some mucus is discharged on the surface of the stone, which gives it a blackish appearance. These, when small, are every now and then passing down through the ureter, while in the kidneys they generally produce very little pain; but in their passage through the ureters the pain they produce is extremely great; the testis on that side is drawn up high, and the scrotum contracted, and the paroxysm is usually attended with sickness and vomiting, and very often with a discharge of bloody urine. These symptoms constantly attend the passage of a calculus through the ureters. When it gets into the bladder, the patient is somewhat relieved; when small, it sometimes gets into the bladder, and is discharged with the urine; but they sometimes remain in the urethra, and become gradually increased in size. When retained for a length of time in the bladder, they gradually increase, by attracting more particles of the same matter, which is formed on the surface, till they

R

are sometimes of considerable size. When in the urinary bladder, and very large, they partake in some degree of the form of the part, and are generally flattened and pyramidal. Here is a cast of one extracted by Mr. Cowell, surgeon of St. Thomas's, weighing 13 ounces. When small, they are various in their form, also in their surface; some smooth, others irregular; sometimes so much as to put on the appearance of a mulberry. Those which are irregular externally are generally more compact in their substance than others. Sometimes there are small spiculi projecting from every part of the stone. The formation of calculi is, I believe, by a process similar to crystallization. The crystals are generally opaque, but in one instance I have seen them transparent. The calculi that can pass through the urethra of the male are of a very small size, but sometimes much larger pass through the meatus urinarius of the female. The colour of calculi is also very various, both in their external and internal surface. Those calculi situated in the urethra, if they become large in size, are always very oblong, and if they chance to be situated in that part of the membrane of the urethra where there is the curve, they take on a proportional curve. The colour of these calculi varies considerably, sometimes being white externally, at others reddish. These stones, when cut through, are composed of a number of strata, one over the other, in numerous layers, from the centre to the circumference, which vary a little from each other in their texture. When large, they vary from the circular direction, adapting themselves to the bladder. The form and consistence of the strata differ very much.

Any extraneous body getting into the urinary canal will form the nucleus of a stone. I have seen a needle in the centre—sometimes a piece of bougie, or a small coagulum of blood, or a small calculus passing from the kidney into the bladder, and remaining there for a long time. Here is an instance of one which weighed 10 ounces, of which the centre alone appeared to be originally formed in the infundibulum. I have seen an instance of two bits of sticks forming the nuclei of two calculi situated in the urethra, which have depressions and risings corresponding with each other. This man had strictures in the urethra, for which he had been in the habit of using bougies, which being without, he made use of a bit of stick for the same purpose, which broke off in the urethra. Here is a stone which Mr. Girdle extracted, having a yellow substance in the centre, and a chalk like appearance externally, which he supposes arose from

taking medicines internally for dissolving the stone: he believed that the lixivium has this effect. Though it does not dissolve the stone, yet it makes the surface softer externally, and relieves the symptoms. We sometimes find considerable variations in the appearance of the calculi, some of the strata differing very considerably from others, great changes having taken place during their formation. This might arise from particular diet or medicine taken at the time. Here is a very curious calculus of three colours; the central one reddish, with a number of small star-like spiral projections around it; then another of a greenish colour surrounding that; and immediately around it a much larger substance, quite white. Here is another instance of a large stone taken out of the bladder of a dead subject, with a mulberry calculus in the centre.

Calculi also very frequently vary in their number: though generally but one, we have sometimes several. It has been observed, that you may generally know, when you have extracted a stone, from its appearance, whether there are any more. When smooth, it has been attributed to there being more than one in the bladder, from the surfaces rubbing against one another. It is so in general, but not always; for where calculi are of a very firm texture, there is often no external appearance of any other being contained, of which Mr. Warner has given an instance, where four calculi, taken out of a patient, were all of them irregular on their surface. I have extracted seven; but the most extraordinary instance was in a patient of Mr. Samuel Sharpe's (Lawrence Welch), of Guy's Hospital, from whom were extracted 214 flakes or pieces of stone. Their chemical analysis is not yet determined; however, it is evident that calculi are not all similar.

Causes of Calculous Concretions.—There is one very common cause—that of extraneous substances being situated in the urinary canal. If they remain there any length of time, get there how they will, calculous matter will form round them. This may happen in a variety of ways, as where the patient has any diseased state of parts, as separation of a small quantity of blood, forming a coagulum or a little nucleus. But there seems a disposition in the kidneys of some persons to form calculi, which is evident in those who have nephritic complaints for a great length of time, who are continually voiding small particles of sand, which, if they were to remain any length of time, would form calculi. A diseased state of the kidney, or peculiarity of action in that part, subjects many patients to the stone. However, in many instances it is an accidental

circumstance, and not from any diseased disposition, as shewn by people who have had the stone, which, being removed, they have had no return of the complaint. Some have supposed that the diet of the patient might contribute to this—the water, or particular food they lived on. Hard water has been supposed to produce this; but I am inclined to think it will not at all contribute to it, unless there is some diseased action in the part, for water or any other substance taken into the stomach undergoes great changes from assimilation; likewise in every thing we eat there is the same earthy substance, which would be equally liable to produce calculi. This earthy matter is contained in the mucus and urine of all persons in some quantity, and it is only from some accidental circumstance that it is formed into calculi. It is dissolved in consequence of the warmth of animal heat, but in becoming cold is separated. Various medicines have been tried to dissolve the stone, but hitherto none have been found to have this effect within the body. Calculi are dissolved in various ways, but a medicine taken by the mouth undergoes such variety of changes that it is very improbable that it should ever retain its solvent power. The medicine which is given may alter the fresh deposit, but not that which was originally formed there. The relief of pain from taking the lixivium is in consequence of the external surface being softened; hence giving less pain when the bladder contracts upon it. (Its use tends to destroy the mucous membrane.) This I had an opportunity of observing in a boy, who had long taken the lixivium. On the instrument being introduced, it was thought he had no stone at all, for it did not give that vibrating shock which is common. The most probable way of dissolving the stone would be by injecting fluids by the urethra, which should be so mild as not to affect the urethra or bladder; but this would be with difficulty effected in a stone patient, on account of the irritability of the bladder. However, it is proper experiments should be persevered in with respect to solvents for the stone, as such a discovery would be a great acquisition.

The symptoms of the stone are very strongly marked, so as to point out the disease. The patient has frequently calls to make water, which passes off in a full stream, but often becomes suddenly stopped while passing, and this before the patient has entirely emptied the bladder, shewing that it has been stopped by some extraneous body getting to the orifice of the urethra, varying its position by the discharge of urine, which is always attended with a deal of pain, and gives a

smarting sensation at the end of the penis. Stone patients, therefore, particularly children, from the great pain in that part, are very apt to take hold of the end of the penis and squeeze it very forcibly, which gives them temporary relief: this causes the prepuce to be elongated, projecting a great way from the glans, so that there is some difficulty in coming at the glans for passing an instrument; also any considerable motion of the body, when the stone is large, is irritating to the surface of the bladder, causing immediately an inclination to void the urine, so that stone patients are incapable of riding in a carriage or on horse-back; however, this is not always the case, for I have known some capable of this, but in such the surface of the stone has been smooth. The considerable irritation which the stone produces prevents patients from getting any rest, so that they are frequently disturbed during the night in order to make water, and perhaps void no more than 3 or 4 times, thus being wakened every hour or half hour; and when the patient has voided his urine, the bladder still contracts, and produces great pain: if this continues long, the bladder becomes so irritable that the patient suffers considerable pain for a length of time. The manner in which stone patients void their urine is rather remarkable, if attended to. They generally place themselves in a particular situation, with their knees separated far apart, and moderately bent, their trunk stooping forward, generally supporting themselves with one hand: from this position in which they place themselves they appear to me to relax all the parts as much as they can. However, we cannot certainly pronounce from these symptoms that the person has the stone, for there are some diseases with symptoms so similar, that it is uncertain till we sound the patient. Of these, we have the diseased prostate, which, when considerably enlarged, produces painful sensations about the neck of the bladder, very much increased on the motion of the body, and frequently stoppage of urine from the alteration of the urethra at that part; also sometimes from a very irritable state of the surface of the bladder when patients are incapable of retaining their urine long. An ulcerated inner membrane of the bladder or polypi may produce symptoms of stone. Strictures in the urethra, while they are forming, will produce symptoms similar to the stone, but this may be distinguished in some degree by the smallness of the stream in which the urine passes.

In searching, we are liable to some deceptions. When the instrument is passed into the bladder, if the resistance of that

organ is great, it gives a firm irregular resistance to the staff, which feels a good deal like the stone; however, they who are much used to searching patients can distinguish this feel from the hard stroke excited by the calculus. Also, if there should be any sand situated in the urethra near the bladder, that will cause a sensation by the medium of the instrument, similar to that of the stone.

Sometimes within the ducts of the prostate gland small earthy matter is collected, giving the same sensation as rubbing the stone; but, in general, a stroke against a calculus produces so strong a vibratory feel, and so distinct a sound, that there can be no doubt as to this point. When it has been ascertained, the next consideration is the operation.

This may be done in either sex and at all ages (formerly it was objected to in very old and very young subjects), unless there is some other disease which makes it objectionable, as where there is a diseased kidney, or stone in the kidneys or ureters: while the patient has any nephritic complaints it is improper, as probably little benefit would arise. It has also been objected to where the patient has been much emaciated, and the strength much exhausted. This does not seem to be any considerable objection, for if you remove the cause of this reduction in the constitution, he often speedily recovers. If there was great reason to believe, from continued pain independent of the fits of the stone, and considerable discharge of pus, that the bladder was diseased, little success could be expected.

The operation in the male subject has been performed in various ways, as cutting on the *grape* by introducing two fingers into the anus, and pressing the stone forwards *in perinaeo*, and cutting upon it, which endangers the division of the urethra and prostate. This is particularly described by Celsus, who says it should not be performed but on subjects between the ages of six and fifteen, as in adults the bladder is too distant to reach. It must appear to every one at all acquainted with the structure of this part, that the manner in which the wound is made would be very uncertain, and much unnecessary mischief might attend this mode of operating.

It has also been proposed to make the incision at the pubes, which is a very exceptionable method. The distension of the bladder may be accomplished in two ways—either by injecting it, or by putting a yoke on the patient some hours before the operation is performed, and allowing the urine to accumulate. Injecting it is often impracticable, for the bladder becomes so thick, as for a length of time not

to be distended to any considerable degree, being so thick as not to admit of it. In the thickened bladder which often attends stone patients the putting on the yoke gives intolerable pain; and also the frequent injuries which happen on cutting into the peritoneum, and the embarrassment which has often arisen in extracting the stone, has quite thrown this mode into disrepute, and now what is called the lateral operation is very generally adhered to. This is done by cutting the perineum on one side, and then extending the incision into the bladder. It has been performed with some little variation by different surgeons, and lately has been attended with great success. Frère Jacques first performed the operation with a success which was very much magnified, and did prove so when he arrived at Paris. His operation was performed with a staff with no groove in it, which must have occasioned great difficulty in getting into the bladder. A good deal of care is necessary in getting into the bladder, to avoid wounding the rectum.

The operator is most conveniently situated opposite the patient. The staff is first introduced, and should not be pressed too near the abdomen, as that would draw the point out of the bladder. In the *male*, the incision should be made *in perinaeo*, of a proper extent to have a command of the bladder, beginning opposite the inferior part of the arch of the pubes, and directed downwards by the side of the anus. This lays bare the accelerator urinæ, through which the incision should be carried. The bulb of the penis should be put on one side, and then cut upon the groove of the staff. The nail of the index finger should be kept upon the opening, until the beak of the gorget is introduced, which should be done standing up; then the gorget divides the prostate laterally, giving room for the introduction of the forceps. When the stone is got out, we should feel if there be another. If hæmorrhage from the internal pudendal artery occurs, use pressure with the finger against the ischium, which, if insufficient, try a compress of lint. Some preparation is necessary. The patient should be in tolerable health, and take a purge the day before, to empty the bowels, and on the morning before the operation a clyster, to have the rectum perfectly empty. After the operation, we should be extremely attentive to the treatment of the patient, to prevent inflammation in any considerable degree. After the operation, an opiate is to be repeated for two or three nights. If colicky sensations, nausea, vomiting, quick hard pulse, &c. arise, venesection and evacuants are indicated. If the pulse becomes at all full or hard, blood should be taken according to the

strength of the patient. Also costiveness should be avoided by medicine from time to time, and it is proper to foment the abdomen, which is most commonly done by Flor. Chamomel. put in flannel bags, and heated by a warming-pan from time to time: this will be more convenient than the steam. Once, in this hospital, we used to put the patient in warm water in a bathing-tub: this was found inconvenient for adults—it required such a quantity of water, and children it terrified. When inflammation has taken place, and is not relieved by evacnants, a blister may be applied to the region of the pubes with sometimes very good effect, by keeping up an irritation. If the wound goes on well, in a few days the urine takes its proper channel; but when it comes earlier by the penis, it is unfavourable; also if the cloths are not frequently moistened. Simple dressings only are required.

We shall next consider the *instruments* necessary, as much will depend upon the construction of these. They should be of various sizes and shapes, from variety of circumstances. The *sound* to search patients at first is round, without a groove, which passes with rather more ease, and is not quite so much curved as a staff. After it is introduced, by moving it upward and downward it most frequently strikes against the calculus, if there is one. But if the bladder is very capacious, and the stone small, it may be necessary to move it from side to side.

The staff should be made with an open groove, pretty large, that you may have good command of it, for the introduction of the other instruments necessary, and more bent than the sound, that it may be prominent *in perinaeo*; also if not much bent it may thrust the point out of the bladder. The instrument being introduced, a common knife is necessary to make the incision; next, the prostate is to be divided with the gorget—the gorgets formerly used were blunt on both shoulders, so that they made their way through by tearing the prostate asunder—a lacerated wound must be attended with a great deal of pain to the patient, and difficulty to the surgeon, and as the laceration will be various and irregular, it will often endanger the tearing through the termination of the vas deferens. Sir Cæsar Hawkins improved the gorget by making a cutting edge on one side; this is introduced with more ease to the patient and surgeon than before, and less mischief to the contiguous parts, but this on some accounts is inconvenient, because it does not make the incision in the most favourable direction, which is obliquely upwards. Another inconvenience is—that the opposite shoulder of the beak being a blunt one, causes a difficulty of introduc-

tion. I have known a cutting gorget of this kind to cut one side of the prostate, and tear the other; therefore I have made some improvement to obviate the difficulty, which is, having the beak on one side; there is only one shoulder, and that shoulder of the instrument is carried directly outward, with a straight edge, which is very easily set, and may be made as sharp as any knife. This instrument will cut very smoothly through the prostate. In an adult subject the breadth of this gorget should be about an inch, which will completely divide the prostate; in very small subjects, as a child, about half an inch; in the intermediate, about three quarters of an inch. These will be sufficient for every subject, but as we frequently have occasion for the gorget more than once, then a blunt gorget will be proper, when there is no occasion for a beak, which sometimes hitches against some membranous part, causing an obstruction to its introduction. Stone forceps are now commonly made with short blades and long handles, the blades moderately bent; the handles do not come in contact with each other, and the inside of the blades are made rough, to take better hold of the stone. The long handles and short blades are attended with this inconvenience, that in taking hold of the stone the handles are much more separated than the blades, which makes the extraction the more difficult, and you are not at all apprised of the force you are making use of; also, from the shortness of the blades, a larger angle is formed; therefore it is with more difficulty drawn out, in proportion to the separation. Also there is great inconvenience from their action while in the bladder: by thrusting these short blades into the bladder, every time you open them, you exert more force against the sides of the bladder than you are aware of, forcibly dilating it thus:—

To prevent this, all forceps should be constructed with their blades and handles of the same length; by these you ascertain the size of the stone, the handles and blades being equidistant, also you are less liable to break the stone, being aware of the force used, it being the same at each extremity, whereby there is no more pressure made on the stone than on the handles, and when in the bladder there is not so much danger of wounding it. The size of the forceps should be regulated to the size of the patient, as ten, eight, or six inches long, which last is the smallest we ever can conveniently use. The size should be such that when the joint of the

forceps is introduced into the bladder, they ought to be situated under the arch of the pubes. The consequence of the joint being either beyond the arch, or not so far as it, is an impediment to opening the forceps. If too short, it is sliding out; if the blades are too long, they are pressing against the sides of the pubes, which thrusts it further in. After the forceps have been introduced, we extract the stone. If a stone breaks in small pieces, a scoop is necessary. There is a groove in the scoop for the purpose of passing the forceps upon it without withdrawing it: if lodged in an inconvenient place, that we cannot command with the forceps, the crotchet is very useful. We have also a *finger crotchet*, sometimes found useful in the same way. When a stone is very small, it may fall from between the blades, when a pair of flat blades is necessary. Sometimes the calculi are so inconveniently placed, that a pair of curved forceps are necessary to get at them.

Extraction of the stone from women.—The bladder in females is more capacious than in males, they having a larger pelvis, and being in the habit of retaining their urine longer; hence the stone is with difficulty found, though the symptoms are well marked, the same as in males: also when they are horizontal, a part of the bladder is situated below the meatus urinarius; hence it is necessary to pass a finger *per vaginam*, to raise it up. A female staff being introduced, it only remains to divide the prostate with a cutting gorget, which is best done laterally and obliquely, downward, thus avoiding the crus clitoridis and vagina. The stone is with difficulty extracted, on account of the capaciousness of the bladder; hence the crotchet is preferable.

No dressings are necessary. If symptoms of inflammation supervene, evacuants may be made use of.

Some say a blunt gorget is preferable, as they retain their urine sooner and better from a lacerated wound. I never knew an instance where the cutting gorget was used, but where the woman could in time retain her urine.

your attention, from the circumstance of the bone having remained displaced for some weeks before reduction was attempted; and they afford me the opportunity of offering you a few observations on the course that ought to be pursued under such circumstances.

Cases of Unreduced Dislocations of the Shoulder.

William Richards, a sailor, 44 years of age, was admitted on February 22, having had his right shoulder dislocated on board ship three weeks before. He was of spare habit, and not robust. No attempt at reduction had been made, and he had continued to perform his usual duties to a considerable extent. The nature of the accident was rendered immediately evident on uncovering the limb, by the unnatural projection of the acromion, the falling in of the deltoid muscle, the distance at which the elbow was held from the side, and the unusual direction of the axis of the humerus in relation to the trunk. The head of the humerus could be felt in the axilla; and the limb was found longer than that of the opposite side by half or three quarters of an inch. The case was that usually called dislocation into the axilla; in which the head of the displaced bone lies in front of the glenoid cavity, and a little below its level. The limb could be moved freely, and the patient employed it without much uneasiness, as he had done since the accident, in underhand motions. The circumstances were altogether so favourable, that no doubt was entertained of accomplishing the replacement. Two days after admission he was taken into the operating theatre, that the limb might be subjected to methodical extension. The scapula was fixed by the broad wadded leather band, which I now shew you, of which the middle was placed in the axilla, and the two ends, having been carried obliquely across the chest and back, were fastened by the cords in which they terminate to an upright iron bar, a little above the level of the opposite shoulder. This wadded leather band, furnished with rings for the application of pulleys, was firmly strapped on the limb just above the elbow, and the pulleys were fastened above the level of the chest, so as to extend, not horizontally, but a little upwards. The points of extension and counter-extension were exactly opposite each other. When the apparatus had been fixed, and before beginning the extension, between twenty and thirty ounces of blood were taken from the arm, and one grain of tartarized antimony was administered in solution; five other similar doses being given at intervals during the process. Extension, first in a moderate, and then in a gradually increased degree, was kept up between twenty and thirty minutes, with the

CLINICAL LECTURE ON DISLOCATIONS OF THE SHOULDER, AND ON SLOUGHING PHAGEDÆNA.

Delivered at St. Bartholomew's Hospital,

By WM. LAWRENCE, F.R.S. &c.

SOME cases of dislocated shoulder, which have lately occurred in the hospital, deserve

effect of altering the position of the bone, which was brought just to the level of the glenoid cavity, but without entering it. The extension was suddenly stopped, the head of the bone being drawn at the same time backwards and upwards, while the elbow was carried to the side. The shoulder had now regained its natural outline, and the reduction seemed complete. The patient was sent to bed, with the arm confined to the side by a broad bandage inclosing the limb and the trunk. When the joint was carefully examined, at the end of three days, it was clear that the replacement either had not been perfect, or that the dislocation had been renewed. The form of the shoulder was improved, and the elbow no longer projected from the side, with which it could be brought into close contact without difficulty or pain. My colleague, Mr. Stanley, agreed with me in opinion that no advantage could be expected from renewed extension, to which the patient at once stated that he would not consent, being satisfied with the use that he had of the limb, and suffering no pain whatever. I now left the limb at liberty, desiring the patient to employ it freely. He left the hospital on the 12th of March, with great improvement in the motions of the limb, which were nearly perfect except in the directions upwards and backwards.

Stephen Bland, 37 years of age, a tall, muscular, and robust man, was admitted on March 16, for a dislocation of the shoulder, which had happened a month previously. No attempt at reduction had been made, the nature of the injury not having been recognized. The projection of the acromion, and the falling in of the deltoid, were less conspicuous than in the preceding case, in consequence of the patient being much stouter; independently, however, of these signs, the nature of the injury was rendered sufficiently obvious by the mode in which the elbow stood out from the side, by the relation of the axis of the humerus to the trunk, and by a slight increase in the length of the limb. The patient had continued to suffer from the time of the accident, and possessed very little power of moving the limb. The same mode of proceeding was adopted in this as in the preceding instance, in respect to extension, counter-extension, venesection, and the administration of tartarized antimony: he only lost, however, about sixteen ounces of blood. When the extension had been continued about twenty minutes, having been gradually raised to a degree which I should not have considered it safe to exceed, the patient said that the bone had gone in, although I had not noticed any change of position. On carefully examining the part, I found reason to believe that the patient's statement was correct; and, on stopping the extension and lowering the limb, it turned

out to be so. I thought it proper to keep the limb bound to the trunk for some days. When it was set at liberty, the power of motion improved rapidly; all uneasiness had ceased from the time of reduction. He left the hospital in a month, and called to see me at the expiration of another month, when the limb had regained its natural strength and freedom of motion, excepting the movements upwards and backwards, which were still limited and imperfect.

George Thompson, 67 years of age, came into the hospital, on May 10, with an unreduced dislocation of the humerus, of eight weeks' standing. Extension was made twice by means of the pulleys, but without success; the motions of the arm were, however, improved.

The preceding cases are calculated to encourage us in attempting to replace bones which have been dislocated for some weeks. We may either succeed completely, restoring the limb to its natural state and utility, or, failing in this, we may give increased power of motion. We must, however, observe some caution in the degree of force that we employ, especially when we use the pulleys, and in its duration. In his valuable work on Dislocations and Fractures of the Joints, Sir Astley Cooper says, "I believe that much mischief is produced by attempts to reduce dislocations of long standing in very muscular persons; great contusion of integuments, laceration and bruises of muscles, stretching of nerves, leading to an insensibility and paralysis of the hand. I have seen follow an abortive attempt to reduce a dislocation of the shoulder; so that the patient's condition has been rendered much worse than before the trial at reduction. Even when the bone is replaced, it is often an evil rather than a good, from the violence of the extension*".

I will cite a few examples calculated to impress this caution more strongly on your minds.

Pelletan† mentions that the axillary artery was ruptured in an attempt made at the Hôtel-Dieu to replace a dislocated humerus at the end of four months.

M. Flaubert, of Rouen—an excellent surgeon, of great knowledge and experience—has met with several unfavourable cases, and has set us the admirable example of recording them for the public benefit‡.

A dislocation of the fore-arm, in which the radius and ulna were thrown back on the humerus, in a woman of 48, was reduced on the 27th day. The dislocated bones yielded suddenly on the third extension, with

* Chap. I. on Dislocation in general.

† Clinique Chirurgicale, vol. ii. p. 95.

‡ In the Répertoire général d'Anatomie et de Physiologie Pathologique, et de Clinique Chirurgicale, vol. iii.

a sound and appearance which led all those present to conclude that the soft parts round the joint must have generally given way. Great swelling of the limb followed, with cessation of the pulse, coldness, and insensibility. General paleness and weakness followed. The patient recovered gradually, but the fore-arm and hand remained useless.

Reduction of a dislocated humerus was accomplished in a woman of 64, at the end of seven weeks. Hemiplegia and partial closure of the eye followed. The limb, which had been without pain, and possessed considerable freedom of motion, remained nearly useless. The hand at least was quite unserviceable; the fingers being permanently half bent, and the two last insensible; the thumb extended.

M. Flaubert attempted the reduction of a dislocated humerus on the 14th day, in a gentleman 60 years old. Great pain and numbness came on in the wrist and hand, the extending force being applied to the former, according to the usual method in France. As those symptoms increased with the continuance of the extension, the attempt was given up. Great pain ensued in the whole limb and in the neck. Shrinking of the member and paralysis were the ultimate results.

A dislocated humerus was reduced on the 11th day in a man of 57. Great swelling of the axilla and shoulder ensued immediately. The patient died fourteen days after the reduction, when the axillary artery was found to have been completely torn across.

In a female, 70 years old, of good constitution, a dislocated shoulder was reduced at the end of five weeks; the reduction being followed by emphysema, severe pain of the corresponding leg, and long fainting. Subsequently, the arm and leg became paralytic, and the patient died on the 18th day. The four lower nerves of the axillary plexus were found matted together by thickened cellular texture, and torn out from the medulla spinalis.

The narratives of M. Flaubert's cases do not enable us to account for their unfortunate results, to which I have seen nothing similar. He never used the pulleys, but was contented with what we consider the milder degree of extending force, exerted by assistants pulling at the two ends of a folded linen. The extension was not maintained for an undue length of time; nor was there any imprudent repetition of it in any of the cases. The extending force was applied above the wrist.

Dr. Gibson, of Philadelphia, has recorded two cases, which terminated fatally from injury of the artery.

In a patient, 50 years old, reduction was attempted at the end of three weeks, after the abstraction of three pints of blood. Ex-

tension was made by five strong men; and the attempt was repeated several times, but ineffectually. Although he had suffered much on this occasion, he was very desirous of submitting to any measures by which the use of the limb could be restored, and applied to Dr. Gibson for this purpose at the end of two months. Two pounds of blood were drawn from the arm, and powerful extension from the carpus, by means of pulleys, was tried three times ineffectually. Three further attempts were made in different manners, two of them with the heel in the axilla. On the last occasion the bone was replaced; but it escaped again in half an hour, when Dr. Gibson finally restored it. Swelling of the axilla came on; then great faintness, and death the same evening. The axillary artery, which had become closely united by coagulable lymph to the capsule at the neck of the bone, was torn across*.

A strong man, of 53, came under the care of Dr. Gibson, for a dislocated shoulder, nine weeks after the accident. Several attempts at reduction had been made soon after the occurrence, with the employment of great force. Reduction was effected after an hour and three-quarters had been employed in extension by means of pulleys and in other ways; twenty ounces of blood having been taken from the arm, and twelve grains of tartarized antimony having been given in the time. Great swelling of the chest with pulsation was found on the next day, and the artery was tied above the clavicle on the following day. The patient survived the operation five days. The artery had undergone a considerable laceration: it had adhered so closely to the capsule and bone that reduction could not have been accomplished without tearing it. There was fracture of the glenoid cavity in this case†.

Von Froriep has related the case of a youth, aged 26, of a wretched weak constitution, with curved spine, who met with dislocation of the right shoulder. He suffered but little pain, and was able, after a few days, to do the slight work he was accustomed to nearly as well as before. He was seen by a surgeon on the 20th day, who advised reduction, and proceeded to make extension by means of assistants. It was necessary to desist, on the first day, from the severe pain experienced by the patient. In a second attempt the extension was followed up in spite of the pain, and the bone was replaced. The reduction was followed by syncope, which did not last long; swelling of the shoulder came on; then repeated faintings; and death followed in about three hours. A great effusion of blood was found

* Philadelphia Journal of the Medical and Physical Sciences, vol. vii.

† American Journal of the Medical Sciences, vol. ii.

in the axilla and neighbourhood: it had proceeded from the axillary vein, which presented a laceration an inch long, but was not completely torn through*.

You will see clearly from these cases, that if we act on the general rule of attempting replacement in all unreduced luxations, and of employing such a degree and continuance of force as may be necessary for accomplishing the object, we shall sometimes leave the patient with a paralysed and useless limb, and sometimes endanger, or even destroy life. The old and excellent rule of taking care to do no harm, if you cannot do good, is here particularly applicable. There is no excuse for such dangerous attempts in dislocations of the humerus, because a new socket is gradually formed for the head of the displaced bone, which gradually acquires so extensive a range of motion as to render the limb very useful. I knew a gentleman with an old unreduced luxation of the humerus, in whom those who were not aware of the circumstance did not observe any defect in the motions of the extremity.

Your attempts, then, in these cases of unreduced dislocation, must be confined within certain limits in respect to the time elapsed since the accident, the degree of force to be employed, and the duration of its application. "I am of opinion," says Sir A. Cooper, "that three months for the shoulder, and eight weeks for the hip, may be fixed as the period from the accident at which it would be imprudent to make the attempt at reduction, except in persons of extremely relaxed fibre, or such as are at an advanced age." This rule is not to be followed strictly; it is only meant as a general guide. There are cases in which it would not be prudent to make the attempt within the periods just mentioned; there are many, in which the attempt will not succeed under the employment of such extension as I should not think it safe to exceed. Remember the rule "*Saltem ne noccas*;" and if the parts have become accommodated to their new position—if the motions of the limb are tolerably free and improving, and there is no pain—take care to do nothing that may put the patient in a worse position. It is possible to reduce a dislocation, and at the same time render the limb useless. I cannot define exactly the degree of force to be employed, which indeed will differ in different circumstances. You should begin with gentle extension, and increase it slowly, attempting to accomplish the purpose by the persevering application of moderate force. You must carefully watch the effects produced on the limb and on the system in each case. I think it can seldom be advisa-

ble to continue the extension much beyond half an hour. If the bone did not yield to one or two attempts of this kind, made under all the circumstances calculated to promote a favourable result, I should not recommend a repetition of effects.

Dislocation of the Humerus, attended with a grating Sensation on Motion, leading to the supposition that the case was complicated with Fracture.

James Yarnsley, 40 years of age, was admitted into the hospital, on the 23d of March, 1838, for an accident to the shoulder, which had occurred on the 21st. A cart, in which he was riding, was overturned; he was thrown violently to the ground, when the cart fell on him, and he remained under it for some time. The gentleman, who first examined the limb, considered that there was a fracture, and therefore recommended that he should be sent from the country, where the accident happened, to the hospital. They who first examined the patient on his arrival entertained the opinion that there was fracture; and the case was accordingly mentioned to me as a dislocation of the shoulder with fracture. The dislocation was obvious enough, and it was soon ascertained that the humerus was not broken. A sensation like crepitus was perceived as distinctly as in a fracture, when the shoulder-joint was firmly grasped with one hand, and the arm moved with the other; also, when the upper end of the bone was raised by the hand passed under it in the axilla, the elbow being held by the other hand. The sensation appeared to me more like the hitch or catch which might be produced by moving the articular head of the bone over an irregular hard surface, than the sharp grating of broken bones: the symptom, however, was so strongly marked as to lead to the opinion that the neck of the scapula was fractured. Never having seen a specimen of fractured neck of the scapula in any museum, and reflecting on the mode in which this portion of the bone is protected against external violence, I conclude that such an injury, if it ever happen at all, is extremely rare, and that it is the least likely to take place when the effect of the force has been spent in causing dislocation. As the existence of dislocation was unequivocal, while I doubted altogether respecting that of fracture, I deemed it advisable to make a cautious trial of extension, which I did on the 24th. When a moderate force had been applied, by two or three assistants pulling at the ends of a folded linen fastened above the elbow not more than five minutes, the bone went in, the mobility of the joint was restored, and there was no longer any crepitus or other indication of fracture.

The head of the humerus, when dislocated,

* Veraltete Luxationen, vom Standpunkte der Chirurgie und Medicinalpolizei betrachtet: Weimar, 1834.

may lie upon the subscapularis, or between that muscle and the bone; or it may be placed in contact with the inferior costa of the scapula, near the glenoid cavity. In the two latter cases, the movement of the head over the bony surfaces, on which it rests, may impart a sensation closely resembling the crepitus of fracture. I remember a case of unreduced dislocation in this hospital, where the crepitus was so distinct that the injury was supposed to be fracture. The patient died: I do not recollect the details of the history, nor the cause of death. The head of the humerus was in contact with one of the ribs, the surface of which was bare.

Cases of Sloughing Phagedænia.

Louisa Gardner, 18 years of age, fully grown, and completely developed in form, was admitted into the venereal ward on April 5, 1838. She stated that she had left her friends, and been in the streets for three weeks, drinking freely during that time, and generally receiving five or six male visitors every day. She had been diseased for a fortnight, at first slightly, but more seriously for the last few days. During the latter period pimples had arisen on the labium, had become red and painful, and then spread into a large sore, which had increased rapidly with severe pain, entirely depriving her of rest. At the time of admission the external organs generally were red, swelled, excoriated, and superficially ulcerated; and there was copious discharge from the vagina. On the left labium, and the neighbouring part of the mons veneris, where the parts were swelled, but not reddened, there was a sloughing phagedænic sore, three inches long by one in breadth, which had attained that size in the last three or four days. The surface, which was excavated and disorganized, reddish, greyish, blackish, and bloody at various points, and bounded by a sharp ragged edge, afforded a copious ichorous and offensive discharge. Excepting that the severe pain had impaired the appetite and rest, the general health was undisturbed. The appearance and expression of the countenance were those of a healthy young person, and formed a singular contrast to the condition of the suffering organs. Pure nitric acid was immediately applied, so as to soak effectively the whole of the disorganized surface. Thirty drops of Tinct. Opii were given to soothe the pain occasioned by the action of the escharotic, with a direction that it should be repeated, if necessary, in two or three hours: and six ounces of port-wine were allowed to be taken in water. The cauterized part was covered at first with dry lint, and then with bread poultice. The pain of the application subsided in a few hours, when the appetite and rest returned. Great care was taken to keep the parts gene-

rally free from moisture by frequent ablution, and the introduction of dry lint between the folds—a necessary precaution in the management of these cases. The action of the acid converted the diseased surface into a light brown firm eschar or crust, about one-third of an inch in thickness, which began to separate at the edge about the third day, and was completely detached in a few days more, leaving a deep excavation of florid healthy granulations, which filled up, and cicatrized rapidly. On the 21st of April she began to take capivi mixture, and to use a sulphate of zinc injection, on account of the vaginal discharge. As the cicatrix, when nearly complete, ulcerated a little, and assumed an unhealthy aspect, she used, on May 7, the black wash, and took a blue pill night and morning. Its healthy character was soon restored, and she was discharged completely cured on the 16th of May.

Mary Harmer, 25 years of age, a young woman with fair complexion and light hair, who had always enjoyed good health, and had lived in service, married in Bath in November, 1836; left that city, and came to London, in February 1837; she travelled on the outside of a coach, became wet through soon after setting out, and was subsequently ill from the exposure to cold in her journey. From this period she experienced vaginal discharge, with soreness of the external organs, which continued to the time of her admission. She suspected at first that disease must have been communicated by her husband, but she could discover no circumstances to justify the suspicion, and expressed herself as satisfied that there were no grounds for it. Three or four small places or pimples came on the buttocks, and broke into one on the 19th of February, 1838, which increased rapidly till the 23d, when she was brought to the hospital. During these five days she expressed herself as having suffered, without intermission, from the most acute pain and fever, which has entirely destroyed rest, and taken away all appetite. An oval sloughing phagedænic ulcer was found on each side, where the buttocks come in contact: the left was fully two inches long by one and a half broad; the right, apparently of more recent origin, was about half the size. These ulcers were excavated, dirty, reddish, yellowish, and bloody, with ragged edges, and a surrounding margin, about half an inch broad, of the brightest red: a reddish ichor of characteristic fetor flowed from them in abundance: there was slight discharge from the vagina, without redness, swelling, or excoriation; and the integuments were in a natural condition between the vagina and the ulcers on the buttocks. The person and

the linen of the patient were clean; while her countenance, demeanour, and language, were marked by an appearance of modesty, and a character of propriety, calculated to authenticate the history she gave of her complaint. The ulcers were intensely painful, the tongue a little white, the pulse slightly accelerated; in other respects, and especially in the appearance and expression of the countenance, the patient might have been considered well. The acid was applied to both the ulcers, as in the preceding case, and an opiate was administered subsequently. The pain of the application went off before night, the patient slept soundly, recovered her appetite, and continued in perfect health. A dose of calomel and jalap was administered on the 24th: meat diet, with a pint of porter daily, was allowed on the 26th. The separation of the eschars disclosed the most healthy granulating surfaces, which cicatrized quickly. An astringent injection sufficed to remove the discharge from the vagina, and the patient left the hospital, free from all local and general malady, on the 2d of April.

John Reid, 32 years of age, a seafaring man, who had been much in hot climates, and suffered considerably from intemperance and illness, had lately returned to England, and been more intemperate than usual. He was admitted on April 30, 1838. Three weeks previously he contracted venereal disease: in a few days after infection, sores appeared on the prepuce, and excoriation was observed on the scrotum and inside of the thigh. The latter had increased in extent in a week. On the 27th, a portion near the centre began to look black, and to be extremely painful. He was brought to the hospital in the night, in a state of great agitation and alarm, with involuntary tremulous movements of the extremities: 40 minims of Tinct. Opii were administered, but did not procure sleep, and he endeavoured to leave the ward under apprehensions of what might be done for his complaints. There were four sores at the base of the prepuce; a larger, with an indurated base, and three smaller; all of them in a favourable state. The outer side of the scrotum, and the corresponding surface of the left thigh, were bright red. In the middle of the fold, between these parts, there was an ulcerated opening, as large as a crown-piece, three-quarters of an inch in depth, with an irregular black surface, and an abundant fetid discharge. Pure nitric acid was applied to the phagedænic ulcer, and afterwards bread poultice: black wash to the ulcers of the prepuce. Fifty minims of Tinct. Opii after the use of the acid.

May 1st.—He slept well during the night, and is now free from pain, which he has not

been for many days. The surface of the sore is converted into a dark eschar. The pulse quiet and regular; skin cool and moist; tongue clean.

3rd.—The separation of the eschar has commenced these two days: he is quite easy, and only complains that he cannot sleep at night. Two of the small ulcers in the prepuce are healed. Pil. Sapon. c. Opio, gr. v. at bed-time.

4th.—The pill procured no rest, which he explains by saying, that he formerly used to take large quantities of laudanum.

5th.—The eschar has separated completely, and left a healthy granulating surface. Meat diet.

10th.—The aspect of the sore is less healthy; the discharge has become thin; there is pain in it, and in the neighbourhood. Milk diet. Black wash and linseed poultice to the sore.

12th.—Pain entirely gone, and sore healthy.

22d.—The sores on the prepuce are all cicatrized.

June 1st.—He left the hospital in perfect health, the cicatrix being complete, except in a small surface not exceeding the size of a split pea.

GLEANINGS FROM THE NOTE-BOOK

OF A

YOUNG PHYSICIAN IN ITALY.

DURING a bleak morning in the month of November, 1837, with the thermometer at 40° Fah., and "the sky alone for a great coat," I plunged into the busy tide of people floating as usual listlessly up the Toledo, and bent my steps towards the "Incurabile"—the St. Thomas's Hospital of Naples. The entrance into this institution is gained by a double row of steps, one on either side of the door; at the threshold of which was now loitering an immense mob of the halt and the blind—leggers of every age and degree, who, with the revolting importunacy of the Neapolitan mendicant, commenced an onset on my devoted person, which I anticipated as little as I could now avoid. The door was wide open, and, fairly within it, some five or six of the most revolting spectacles, still retaining enough of its appurtenances to declare their connexion with human nature, were congregated, and stunning the very ear as one passed with their beseechings for charity. In no civilized country, perhaps, are the miserable shipwrecks of *lupus*, of *cancer*, and

syphilis, permitted to appal the public eye so unreservedly as in the streets of a Neapolitan town. Medical man as I was, my very blood would now and then congeal within my veins as I came unexpectedly on some frightful specimen of the ravages of these affections, with little more remaining than the mere outline of a face. But let me walk into the portal of the hospital. Here I at once found myself flanked on either side by a row of beds, whose extensive range the eye was scarce able to scan. And those who may be ignorant of the fact, will be surprised to learn, that the miserable patients in the interior are (according to their vicinity to the door) within arm's reach of the dreadful objects I have just described without. The huge door opens widely its jaws, so that, saving the flight of steps without, there is no intervening link between the victims of disease (the miserable inmates of the hospital) and the external world. They are only, indeed, another species of *Punchinello* to the rabble in the streets, and might offer as fruitful sources of entertainment to the curious and the idle, were it not that the spectacle is no longer a novelty.

Along the aisles of this gigantic hospital, the stranger's eye encounters much to surprise, and not a little to offend it. *Imprimis*, I may remark, that, saving the wards set apart for the reception of the consumptive, there appears to be no order or system in the distribution of the subjects of different diseases. The interior of the building being laid out in galleries or aisles, instead of separate wards, as with ourselves, there is an entire absence of that general appearance of comfort which characterizes so remarkably the hospitals of our own country. Here the subject of fever—of inflammation, chronic or acute—of skin disease—of *syphilis*—this man, whose leg was amputated to-day, or that one doomed to the knife to-morrow—all are huddled indiscriminately together; and no one wretch pays the debt of nature around, whose grim corpse is not paraded before the eyes of a hundred other human sufferers. If it is purposed to submit any one of these poor creatures to an operation, he is quietly carried from his bed to the nearest window, where the knife is brandished before the surrounding patients, and glutted with its victim's blood under their eye. This is no exaggerated picture, for I have beheld it more than once myself.

The natural result of such uncivilized and inhuman regulations is, that the lowest wretch in Naples would prefer dying of his malady in the streets, to trusting himself within the precincts of the *Incurabile*. I could individualize at least six instances wherein I offered my purse and person in getting such helpless beings into this establishment, but in every one of which the mention of the *Incurabile* produced in their minds an involuntary shudder of disgust.

Swarms of priests, students, and professors, loitered idly up and down the aisles of the building; and I need only mention they were Neapolitans, to convey some idea of the state of quiet enjoyed by the patients around. Passing on, I perceived that mercurial ointment, which is in high favour here in syphilitic affections, is introduced into the system by innunction over the internal malleolar region. This is effected by means of a stiff leathern glove, without fingers, which fits loosely to the hand.

Still further on, my ear was greeted by a hundred voices, squalling to the tune of some appointed hymn,—the last note (so characteristic of the melody of a Neapolitan songster) grating on the ear with the long drawn and harmonious cadence of an expiring bag-pipe! This vocal display I found to emanate from the beds of about fifty juvenile patients, in the centre of whom arose in solemn array the greasy figure of a skull-shaved priest, who was doling out successive portions of his subject, at the rate of three or four words per minute. Great must have been the luxury of this spiritual balm to the surrounding sufferers in the flesh, more particularly to any such as may have been the subjects of cerebral disturbance, or nervous affections, strictly so called!

Sufficiently satisfied with the arrangements I had witnessed on the ground-floor of the hospital, I now bent my steps towards the "*primo piano*," on the story immediately above, where the female patients were disposed of.

But here I met with a check I had little anticipated. Not even a student of the institution, I was informed, could gain access to this department without a special *bullèta* from Prince O—, a Minister of State, and supreme head of the *Incurabile* Council. Having had the honour of being introduced to that

nobleman, I sent in my card, requesting an order to visit the sanctum in question, which was very courteously granted me. The arrangements in this quarter I thought very superior to those I had lately witnessed below. There was here a general air of cleanliness and comfort pervading the place; and the assiduous attentions of the nuns of a neighbouring convent (who in their formal and faultlessly neat raiment officiated as nurses, *ex officio*) contributed much to heighten the interest of the scene, at least in the eyes of the Protestant stranger.

There is yet another little spot in this hospital I was introduced to, which I shall remember to the latest moment of my life. I allude to that portion of it set apart for the reception of the consumptive.

So great (I may premise in this place) is the dread and the conviction of the contagious nature of phthisis in Italy throughout, and especially in Naples, that, in the latter territory, it is an understood compact between landlord and tenant, that, on the demise of any relative of the latter from this disease, the interior of the house he occupied shall be repainted throughout, and the furniture destroyed, the lessee of the property being chargeable with the expense. With such feelings as these on the part of the nation, it is not surprising that the governors and professors of an institution like the Incurabile should have taken the most effective and potential precautions to guard against the consequences of phthisical contagion.

As I entered this condemned cell, (whence the traveller seldom returns that has once been doomed to its interior), a feeling of horror ran through my veins, as my eye encountered a formal row of sixty or seventy beds, tenanted by as many members of the opposite sex, of all forms and ages, from "the child in its teens" to the mature baby of a greater age.

Here I beheld this appalling disease in all its most hideous shapes. How fatally characteristic the pearl-white sclerotic, throwing into greater relief the brilliant cornea and iris; the whole sunken far within its hollow socket, and manifesting the varied expression engendered by the sufferings, or engrafted by the peculiar temperament of each individual patient. The deathly pallor, relieved in some

cases at intervals, by the hectic line or flush; the teeth of alabaster, the emaciated frame, and above all, the fever of the mind, that stood forth conspicuous on the wreck; whilst, ever and anon, some younger and fairer form than usual attracted my attention, on whom the despoiler's hand had as yet imprinted but the earliest stamp of death—yes, of death, but lovely in its mortality—such an impression as the poet has beautifully portrayed in the words—

"Her brow was fair, but very pale,
And look'd like stainless marble; a touch,
methought, would soil
Its whiteness. On her temple one blue vein
Ran like a tendril; one through her shadowy
hand
Branch'd like the fibre of a leaf away."

A similar ward to this was devoted in another part of the "Incurabile" to the cases of phthisis amongst the men.

But I have yet to mention the more particular object of my visit to the "Incurabile" on the present occasion. I had bartered the preceding day with one of the underlings of the establishment, for a "subject" whereon to run over some of the most important operations in surgery. And, true to his engagement, my friend of the "dead-house" was in waiting upon me—at the *portone* of the hospital long before my ramble in its interior had been completed. Those who are ignorant of the worthlessness attached to the mortal portion of our frame in Italy, when it has ceased to enshrine the living principle of our nature, and who know not how it fares with the dead at Naples, will be disposed to deem me trifling with their seriousness, when I mention that the sum demanded of me on this occasion amounted to six carlini—in our money about two shillings; and that in virtue of my nativity I was here allowed to pay at least twice as much as is the ordinary standard of payment amongst the resident students. The compact thus being arranged, I was conducted into a repository set apart for the reception of the bodies, prior to their being selected for the dissecting-rooms, and where, it was arranged, I should carry on my work. I followed closely in the steps of my cicerone, who led me through a narrow and dismal passage by the aid of a candle, encouraging often my reluctant steps, with an "*audiam*," as the gloominess of the perspective began to abate my eagerness to proceed. The door was at length opened, and I heard

it grate again heavily on its hinge, before perceiving the nature of the place. But there was no retreat open to me; so I set about analyzing its recommendations. Imagine a cell or dungeon averaging about 10 feet by 8, whose only ray of light was derived from a cornuscation that crept through an arm-hole above the door, which, again, was almost neutralized by that thrown out from a dismal rushlight, lodged in the body of a potatoe. Raising my eye from this illumination to a survey of the apartment itself, I beheld a line of human carcases, reposing negligently around its circumference, consisting of men, women, and children, as might be, locked in the arms of one another, and exemplifying not the blind leading the blind, but the dead caressing the dead. In the centre of the chamber, on the other hand, there arose, in huge and grisly relief, an immense cart on two wheels, whose exterior displayed a rich coating of gory blood combined with a due proportion of mud. But I had little leisure to contemplate this interesting spectacle, when a footstep approached, and a suppressed cry of "Paolo, Paolo," greeted my ear. The bolt was withdrawn, and a brother promoter of science introduced himself to my notice. The look with which they encountered each other I thought most significant, as if they would have wished to say, an Englishman is not to be entrapped every day. I gazed on these "Arcades ambo" (that is, blackguards both) with reflections far from satisfactory; but a sudden air of business recalled me from so ill-timed a reverie. The pin was removed from the head of the cart, the tail-board withdrawn, and my two friends fixing their shoulders against its head, a stream of fifteen or twenty bodies, of all ages and sexes, floated gracefully "heads and tails" over one another, and the next moment landed on the ground before me. "*Guardate, signor, guardate!*" they exclaimed simultaneously, with a grin of satisfaction. "*Buon, signor, buon!—sono eccellenti!*" "*Scegliete che volete!*" But I had seen enough; and leaving science to take care of herself, I flung down some carlini over and above the sum I had stipulated for, and hurried from a quarter fit only for devils to inhabit. I was subsequently informed, that the dead-carts at night, on their way to the Campo Santo, deposit one always at this cheer-

ful repository for anatomical pursuits, from which are selected, the next day, as many as may be required, and the surplus then conveyed in the same manner to the dead-pits of the Campo Santo!

But let me turn round the picture a little to the light, and look at it on its fairer side. Leaving behind me the spot where "the wicked cease from troubling, and the weary are at rest," and seeking to forget in the unceasing uproar and endless variety always to be met with in the streets of this city, the gloomy impressions of so infernal a spectacle, I happened to stumble across the path of my excellent friend, Professor Quadri, ophthalmic surgeon to the Military Hospital, and Professor of that branch of surgery in the University of Naples—to which gentleman I was indebted, during my residence in that city, for many acts of courtesy and attention. Knowing I was about to take my departure from Italy, the Doctor begged to know if I had been introduced to Assalini since my arrival; and being answered in the negative, proposed I should now accompany him to the house of the old man, who, from a lively recollection of his visit formerly to England, would be pleased to receive me. So we stepped into the carriage together, and in a few minutes afterwards alighted at his door. The abode of Assalini was little enough like what one expects to find in a palazzo, strictly so called; and the humble suite of rooms I passed through within was no less in keeping with its exterior. I found the good old man sitting up in bed, his nose bestraddled by a large pair of horn spectacles, and himself closely engaged in reading the life of Cicero—deeply lost in the interest of his subject, if I might judge from the earnestness with which his eyes were riveted on its pages; for he did not seem to notice our entrance till my friend touched him gently on the shoulder, and informed him of my presence. The old man turned down the leaf in his book, removed the spectacles from their resting-place, and shook me cordially by the hand. When acquainted with the object of my visit (for I observed to him that I was anxious to be able to tell my countrymen, on my return to England, I had seen and conversed with the great Assalini), a smile of conscious satisfaction played around

his lip, whilst his fine features all grew into action in beholding me. "See, signor," said I, "we have never been able to rival, or even come up in our inventions to your excellent instrument, which is the pocket companion of every surgeon in England to this day;" and I opened my Cooper's case (which I had brought with me in the morning to employ at the Incurabile), and placed "Assalini's forceps" in his hand. "Very good, sir; very good," said he (for he conversed in excellent English), "I believe there is some merit in the idea; but this is, indeed, a beautiful little specimen of my instrument. We cannot make them like this in Italy;" and he sent for a large case of various instruments, of the rudest material and design, with which the rust of time seemed to have been busy. Out of those before us, he selected his own forceps, which rather resembled an article we should look for in a blacksmith's forge than a surgical instrument. He shewed me a great variety of forceps for lithotomy, many of which he told me were of his own invention. Indeed, I was made to understand that nearly every article in the case had been designed, or subsequently improved upon, by himself. I soon perceived the old man had mounted a favourite hobby, on whose back every moment rendered him more discursively eloquent; so much so, that I began to despair of seeing him again dismount, when my eye fell by accident on the Surgical Dictionary of Samuel Cooper, occupying its place amongst a choice collection of books. This stratagem exceeded my expectation, for he seized the work with avidity, and turned over its pages, in fifty different places, to display the mention of his own name. He spoke with great pleasure of this work, as well as of its author, whom, however, I thought he appeared to confound with Sir Astley; for he did not apparently recollect our having two surgeons of that name.

I found Assalini most eloquent on the subject of his residence in London; and great were the eulogies he passed on the celebrated men of the profession he had there known, and his praise of our hospital and school arrangements was unbounded. With a pleasing frankness of manner he attributed much of his subsequent success in life to the information he had acquired in England, through the facility of obtaining know-

ledge at our public institutions, and from his intercourse with the leading surgeons in the metropolis.

I had now been nearly half an hour conversing with Assalini before we either perceived that the exertions he had made were becoming too much for him. The old man had felt himself once more amongst the scenes he was recounting, and was supported under the momentary excitement by feelings akin perhaps to those he then possessed. But he had unconsciously fallen back on his pillow, overcome by his natural enthusiasm of manner, and the interesting nature of our subject; and when I rose to take my leave, he did not offer to detain me.

He told me, in the course of conversation, that old age and a sensible declining of the powers that once animated him, had driven him from the north of Italy to seek support from the serenity of a Neapolitan sky; and that having played his little part on the great stage of human life, as he hoped, with credit to himself and advantage to society, he had tranquilly retired to his bed, from which he was not again anxious to be removed, and where, with such a companion as Cicero to cheer and instruct him, he was prepared and hoped to meet death as should become a good and great man.

I was truly affected with this pathetic soliloquy, delivered as it was with the greatest serenity of manner and composure of mind; and which (pressing my hand firmly between his own) he slowly uttered, with beautiful simplicity, a faultless purity of language, and admirable firmness.

M. B. S.

[We sincerely hope that the "Young Physician" will favour us with a few more "gleanings."—ED. GAZ.]

ON THE TREATMENT OF BURNS AND SCALDS.

To the Editor of the Medical Gazette.

SIR,

IN THE MEDICAL GAZETTE for the 13th of October last I observed an account of a new method of treating burns, related by Dr. Greenhow, in which that gentleman recommends that these injuries

should be dressed with a mixture of resin ointment and turpentine, applied in a melted state, so as to form a complete coating, which is to be left on till the parts are healed. This account of Dr. Greenhow's gave rise to the relation of another plan by Mr. Leach, who extols the use of treacle as a dressing for burns. I am induced to make a few observations on these methods, and on the treatment of burns and scalds generally, in consequence of the great diversity of opinion which exists among surgeons on this subject.

There is perhaps no affection in which so many different modes of cure have been practised as in burns, each individual or school professing to have some infallible remedy, which they employ indiscriminately in all stages and degrees of these injuries, and which, though they may sometimes do good, are more often productive of mischief. Burns have been divided into several different varieties or forms, according to the degree of injury, which may vary from slight rubefaction of the skin to complete destruction of all the tissues of a part, according to the temperature of the burning substance producing the mischief, and the duration of its application. These divisions might be multiplied *ad infinitum*, no one degree being separated from another by any marked line, but each running into the next by imperceptible gradations. They may all, in fact, be comprised under two heads, viz. inflammation and actual disorganization, of which changes all the other varieties are only modifications, both of these effects differing greatly in degree. In some cases, though the heat applied be not sufficient to destroy the life of the part at once, yet the inflammation produced may be so violent as to lead to mortification afterwards; and at the time of the reception of the accident, or immediately subsequent, it is not always possible to know what may be the extent of the injury, as the skin may retain nearly its natural colour, though the parts beneath have lost their vitality. From this circumstance of its often taking some days to develop the severity of a burn, the vulgar notion has arisen that the action of the fire keeps progressing for nine days.

In serious burns (and these injuries are generally more dangerous in respect to their extent than their depth) there

are mostly very violent constitutional effects immediately produced, as acute pain from the sentient extremities of numerous nerves being injured; and this by sympathy causes great disturbance of the whole nervous system, giving rise to depression of the circulation, shivering and coldness, aggravated by exposure to the air, which is frequently followed by great difficulty of breathing, vomiting, and coma.

This sudden shock is the first and most dangerous symptom to be apprehended from a severe burn; but if the patient should recover from the immediate effects, other consequences may follow, the result of which are scarcely less to be apprehended. The two most serious of these are secondary inflammation, producing mortification and violent symptomatic fever; and excessive and long-continued suppuration, wearing the patient out by irritation and hectic fever.

We shall briefly pass in review the principal modes of treatment which at different times have been proposed and practised in this branch of surgery, before we make any remarks of our own. Two entirely opposite methods have in almost all ages been pursued—the cooling and the stimulating—both of which have the support of antiquity; and it is singular that practitioners are not agreed which of these is most efficacious, or whether one is more advantageous than the other under different circumstances. Comparative trials have never been made on a scale of sufficient extent to determine this question.

Cold has been long employed to diminish the inflammation of superficial burns. Rhazes directs that in recent cases cloths dipped in cold water, or water cooled with snow, be applied as soon as possible to the parts which have been injured, and that they be removed from time to time. Avicenna says that this practice often prevents the formation of blisters. The principal advocate for the cooling plan among modern surgeons has been Sir James Earle, who employed cold water, or rather ice, in many cases of extensive and deep burns with the best effect*. The burnt parts may be plunged into cold water, or merely covered with wet cloths repeatedly changed; and this should be

* Essay on the Means of Lessening the Effects of Fire on the Human Body. 1803.

continued till the pain has entirely ceased, which will often be many hours. The common vulgar remedy of scraped potatoes is a very effectual mode of applying cold. Refrigerant applications, however, seem principally applicable to slight cases, where a great extent of skin is not injured; for in the latter instance great caution is necessary in their use, as they will aggravate the shivering and depression of circulation.

The stimulating plan of treatment claims the sanction of greater antiquity than its rival. Aristotle recommended it. Celsus advises the use of stimulants in the first stage, and afterwards the use of mild dressings: he says, speaking "De Adustis," "*Sed dividi quoque curatio potest in ea quæ mediocriter exidentia, reprimantiaque, primò et pustulus prohibeant, et summam pelliculam exasperent: deindè in ea quæ lenia ad sanitatem perducant.*" — (Lib. v. cap. xxvii.) Paré, Fabricius de Hilden, Heister, Callisen, and others, recommend the burnt part to be held to the fire, or plunged into hot water; but this heroic treatment produces violent pain, and never has been much practised; it is contrary to all reasoning. Doubtless slight cases may get well thus managed, but then they would recover equally soon if left alone, or treated in any other way. Spirituous and resinous applications, as spirit of wine and turpentine, were recommended by many of the old surgeons in the first stages of burns; and were revived by Mr. Kentish, who based their use on some strange fanciful theories of analogy between burnt and frost-bitten parts. He thought that as in one the heat should be gradually raised to the natural standard, so in the other it should be lowered with equal care. He first applied very stimulating fluids heated by the fire, which were succeeded by others becoming gradually milder. With this external treatment he combined the internal administration of stimulants, combined with opium, to allay the pain. Though his theories were visionary, yet his treatment will be productive of benefit, in many cases, particularly where the injury is very extensive.

Greasy applications have always been extensively used in the dressing of burns; they were recommended by Hippocrates. Rags dipped in olive or linseed oil, and gently laid over the part, are a simple and safe remedy, and ex-

clude the air. Carron oil, composed of equal parts of lime-water and linseed oil, is a very old application to deep and serious burns, and gained great celebrity, particularly where the skin had been considerably destroyed, as by the explosion of gunpowder. B. Bell recommends this liniment as an emollient dressing in deep burns. Mr. H. Earle advises the use of carron oil in those cases where the cuticle is raised or denuded, but the skin not destroyed: he advises that vesications be left alone, without they are very much distended. Where sloughs are formed, Mr. Earle preferred the stimulating plan in the first stage. Mr. Kentish combined the use of greasy substances with stimulating liquids. After bathing the burnt parts with heated spirits of turpentine, he applied a liniment composed of resin cerate, softened with turpentine, which he spread on linen. This liniment stops the pores of the cloth, impedes evaporation, and thus confines the effect of the spirit to the burnt surface. Mr. Greenhow's plan is essentially the same as this, only he spreads the ointment much thicker, and on the skin itself, and leaves it undisturbed; whereas Mr. Kentish orders the dressings to be removed once in twenty-four hours.

Many other greasy applications in the form of various ointments have been employed in burns. Baron Larrey dressed all deep injuries of this kind with saffron ointment, which he says diminished the pain, and excluded the air; he continued this remedy till suppuration had taken place. Delpech recommends that large ulcerated surfaces from burns should be dressed with opiate cerate.

Mr. Cleghorn introduced the practice of applying vinegar to burns. He says that it should be put on immediately, and its use continued till the pain has ceased. Afterwards, if sloughs were formed, he covered the parts with a poultice, sprinkling powdered chalk on the ulcers, to absorb the moisture. The use of cold vinegar has been recommended by some surgeons since Mr. Cleghorn's time, but its action is simply refrigerant, and it can possess little advantage over cold water, or saturnine lotion. If it is used warm, as Mr. Cleghorn sometimes recommended in very cold weather, it can merely act as an emollient, or perhaps be slightly stimulating.

Astringents, sedatives, and demulcents, have been made use of; the latter have been chiefly applied, after the first effects of the injury have gone off, and inflammation has followed. The principal remedies of this description which have been employed, are a decoction of quince seeds or linseed applied alone, or mixed with a decoction of poppy heads. Emollient poultices have been much used in deep burns; sometimes applied immediately after the reception of the injury, and at others not till after a previous use of turpentine dressings. The diluted solution of subacetate of lead has been thought to prevent the formation of blisters. Whether this effect is owing to its sedative properties, or only by its being astringent, is doubtful; if the latter, equal benefit may be derived from a strong solution of alum, which has also been frequently used.

Compression of the burnt parts with a circular bandage wetted with some astringent lotion, as liquor plumbi, has been employed by M. Marjolin and M. Bretonneau (*Thesis, à Paris*, 1815). The pressure is stated to ease the pain almost immediately, and to arrest the progress of the inflammation. M. Reichenhack (*Bulletin Général de Thérap.* Oct. 1833) recommends the bandage or compresses to be soaked in a solution of *creosote*, which he says hastens the healing process. M. Lisfranc (*Revue Méd.* June 1836) employs a solution of *chloride of lime* with the same intention. M. Velpeau uses strips of lead plaster instead of a bandage, and he thinks that the beneficial effects which he has found to follow this practice are not entirely owing to the pressure exerted on the parts, but must also be referred to some peculiar properties in the plaster, as he did not find the use of a simple bandage equally efficacious.

Of all the more modern plans of treating burns, none have excited more attention than the application of raw cotton. This remedy was first used in America, but the most extensive trial of its efficacy was made by Dr. Anderson, of Glasgow, who applied it in all degrees of burns with the greatest success. It is necessary to put it on with some care. It should be finely carded, and applied in thin layers, several of which may be placed over each other, and then it is generally useful to support the whole with a bandage. Dr. Anderson found this mode of treatment ease

the pain, calm the general disturbance, stop the progress or occurrence of inflammation, and prevent its consequences, as sloughing, suppuration, and subsequent contractions. When there were large vesications formed, he first pricked them.

The powdered flowers of the *typha*, or cat's-tail, which principally consist of soft silky hairs, have been applied to burns in the same way as cotton by M. Vignoles (*Thèses de Paris*, 1833), but they cannot possess any advantage over that substance, and are not so readily obtained.

Another remedy, which certainly has the advantage of being always at hand, is flour. This was recommended by Dr. Ward, of Manchester, to be thickly coated all over the burnt parts, which are to be then covered with lint. This will form a very impervious case, the moisture from the skin forming the under stratum into a kind of paste, which afterwards hardens.

Mr. Cox, in the *MEDICAL GAZETTE* (vol. x. p. 672), recommends the nitrate of silver to be rubbed over the burnt skin, where it is only inflamed or vesicated, before any other application is made. He found this treatment hasten the process of cicatrization, and prevent the occurrence or progress of inflammation. MM. Berot and Cloquet say that burns should be treated like any other active inflammation, by the application of leeches in the first instance, and other common antiphlogistic measures.

The last new remedy the use of which has been made known to the public, is treacle (*MED. GAZ.* Nov. 3). Mr. Leach says that this is to be applied in the slighter cases of burns only. This gentleman considers that his plan bears a great analogy to that of Dr. Greenhow, but I confess that I cannot see it. In the first place he applies it cold, and calls it a "refrigerant liquid," which will "cool the inflamed part." Now Dr. Greenhow applies his ointment warm; and from the turpentine and resin it contains, it must be a stimulating application. In the second place, Mr. Leach does not say how long his treacle dressing is to stop on; but mentions that, in common cases, he applies it on strips of calico, in M. Velpeau's way. By this I suppose he removes the treacled straps every two or three days, as M. Velpeau does the lead plaster; whereas Dr. Greenhow leaves

the ointment on till the parts are healed beneath it. Lastly, Mr. Leach does not recommend treacle to be applied in deep injuries from fire; while these seem the cases most benefited by Dr. Greenhow's system, which he says prevents suppuration even in those cases where extensive sloughs have separated.

Having enumerated most of the plans which have been proposed and practised in the cure of burns and scalds, I shall make a few remarks on this branch of surgery, in which I shall endeavour to shew that these injuries should be treated on general surgical principles, and not be regarded as specific injuries requiring any peculiar plan of treatment. If the surgeon has these principles clearly before him, the means by which he arrives at the desired end are of little importance. The principal indications to fulfil in the treatment of burns are to give ease to the patient as quickly as possible, by calming the pain and cutaneous irritation; secondly, to prevent or moderate the inflammation and suppuration; and lastly, to guard against deformities from the contraction of parts in healing.

In trifling cases, where the skin is only reddened or slightly vesicated, and the surface burnt not very extensive, it is of little importance what means we adopt, as they will get well nearly as quickly in one way as another; but the most rational treatment, and the one which causes the most immediate relief, is the application of cold, either by simple water or saturnine lotion, the use of which should be continued till the pain entirely ceases. In more extensive injury, where the skin is denuded or destroyed, and the parts beneath have perhaps lost their vitality to a considerable depth, what plan will most effectually prevent the occurrence of inflammation and suppuration? In all injuries where, from the destruction of the cuticle, the skin and other tissues are exposed, the most active cause of irritation is the contact of atmospheric air; therefore our endeavours should be directed to those means which will most effectually exclude it. On another occasion (*MED. GAZ.*, July 8, 1837,) I stated that the most successful plan of treatment in incised and many contused wounds is to dress them, so as entirely to keep out the air; and the late Mr. Earle, in his clinical lectures, and paper in the *Medico-Chir. Trans.*, makes

the excellent remark, that this is the first principle to be kept in view in the management of burns, and he advises that whatever dressings are first applied, they should not be too soon removed. In cases where there are large vesications formed, but yet the skin is not denuded, it is of great importance not to remove the cuticle, as this is a very effectual covering from the air, and the fluid effused will often be absorbed, and the cuticle peel off, leaving the surface quite healed beneath it. If these blisters be very much distended, they may be carefully punctured with a needle. The principle being acknowledged that the exclusion of air is the great object, we must inquire what is the most effectual application for this purpose: and I may here remark, that it is a great pity that surgeons will not follow up some of the plans already tried, without being so anxious to discover something new. From my own observation, I am inclined to give the preference to cotton, applied in the way Dr. Anderson recommends, as this will form a very effectual covering, comfortable to the patient, easily kept on, and not liable to be disturbed by the movements of the part: as he says, "it excludes the air; by the slowly conducting power of the cotton, the heat of the part is retained, and a soft and uniformly elastic protection from pressure is afforded: it also forms a sheath or case, which absorbs the effused serum or pus, and gives the best possible substitute for the lost cuticle; but in order that the full benefit may be derived from this substitute, and to ensure an equable and continued support to the tender parts, until the new skin is formed, it is absolutely necessary that the cotton should not be removed, except under particular circumstances, until the real cuticle is sufficiently formed to bear exposure."

If this substance is not immediately to be obtained, the best substitute is flour, which when moistened by the discharge from the skin, or by fluid, with which the surface may first be wetted, will make a hard impervious case. It would probably be a very good plan to strew a layer of flour over the part, before the application of cotton, in all cases, as this would prevent the discharge from soaking into the covering. I am not quite so sanguine as Dr. Greenhow, to think that the exclu-

sion of the air will prevent the occurrence of suppuration in *all* cases; but I know from experience that it will in most.

With respect to that gentleman's mode of dressing these injuries, it is based on true surgical principles, but it seems open to some objections. In the first place, it will not form nearly so effectual a covering as the pitch which suggested the plan to his mind; for the ointment, containing a considerable quantity of grease, the heat of the parts will keep it continually soft; and where the injury has occurred on the posterior surface of the body, or on a part on which the patient cannot be prevented from lying, this cause must operate to such an extent as to disturb the integrity of the covering. In the second place, the application of resin ointment with turpentine is stimulating; and though this may be advantageous in the first instance, it will do no good afterwards, and will be less beneficial than a mere mechanical impervious covering. But as Dr. Greenhow has found this plan so successful, and uses it on the principle of excluding the air, he is quite right in continuing it, and making it known to the public, as the means are of secondary importance if they fulfil the end desired.

It is well known, that in extensive injuries from fire, there is great constitutional disturbance occasioned, particularly coldness and oppression of breathing. This latter effect is generally considered to be owing to suspension of the secretion of the cutaneous perspiration from the injured skin, by which means a greater quantity of watery fluid is carried to the lungs, causing their oppression; but this cannot be entirely the case, for one office of the cuticle is to prevent too rapid evaporation from going on from the surface of the body, and where this covering is destroyed, a greater quantity of fluid will pass off in this way, which may partly account for the great coldness and depression of the circulation. When an impervious coating of cotton, or other substance, is covered over the skin, the coldness and oppression of the lungs are often immediately relieved, as well as the pain, though the cutaneous exhalation must be more completely impeded. On this account I think that the difficulty of breathing must be referred to the injury of the nervous sys-

tem, and the obstruction of the circulation.

I shall not say any thing here on the constitutional treatment of burns; this must be regulated according to the circumstances of the case, as in severe injuries from other causes. Stimulants, with opium, sometimes do good in the first instance, by relieving the pain and depression; but the tonic plan should not be continued too long, as it often does harm.

Contractions, arising from the absorption of the granulations after cicatrization, must be obviated, by keeping the part in an extended position, as Mr. Earle recommends, till the healing process is quite completed.

I am, sir,

Your obedient servant,

R. H. MEADE,

Lecturer at the Middlesex Hospital, and Surgeon to the Western General Dispensary.

15, Bentinck Street, Manchester Square.

RANULA CURED WITH CAYENNE PEPPER.

To the Editor of the Medical Gazette.

SIR,

THE following may be interesting to some of your readers, if, as I believe, the mode of cure is not mentioned in any book, nor adopted in modern practice.—I am, sir,

Your obedient servant,

GEO. HARRISON.

4, Great Marlborough Street,
Nov. 8th, 1839.

The butler, in a family which I attend, consulted me last April for a swelling in his tongue. The tumor was imbedded in the substance of the organ, a little to one side of the median line, had existed for some weeks, interfered considerably with mastication and deglutition, was excessively painful, and, when I felt it, was as hard as, and about the size of, a large marble. On the spur of the moment, and wishing to avoid the operation for ranula, I advised him to put some strong Cayenne pepper on the surface of his thumb and fore finger, to compress the tumor tightly, and to keep them there as long as he was able. Perhaps the old maxim (which I have read somewhere) recurred to my mind—

"Est melior medicina manūs quam quod medicus dat."

The consequence was, that an immense salivary discharge immediately ensued, which, in the course of three or four hours, amounted to two large cupfuls, as described to me. In three days the tumor had entirely vanished, nor, up to the present time, has there been the slightest tendency to a return.

MEDICAL GAZETTE.

Saturday, November 17, 1838.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

LONDON UNIVERSITY DEGREES.

In a previous number we considered the proposed regulations of the London University only so far as the education preliminary to the attendance upon medical lectures and practice is concerned. We come now to the purely professional part of the education, in considering which it must be borne in mind, that it is intended for a class of well-educated and accomplished young men, the sons of persons moving in a higher class of society.

We feel bound at once to state, that this part of the curriculum presents some improvements upon that which we commented on last July. Our correspondent, C. L., then charged us with unnecessary severity in the remarks which we made; but we willingly bear his censure, in the assurance which we feel that but for that severity, and the cordial assent which our observations received from all who were well qualified to judge in the matter, the alterations now effected would never have been made, but the scheme then proposed would have been adopted, though it could not have been carried into effect.

In the present report, we find that

although no course of lectures, except that on practical pharmacy, has been expunged, some of the others have been shortened. Yet even now there is a most absurd superfluity. Although no one has ever supported with a shadow of reason the prodigious demands made by the Apothecaries' Company for attendance upon lectures; yet the London University surpasses even them. Comparing this part of its curriculum with those of the College of Surgeons and the Apothecaries' Hall (for with those of Oxford and Cambridge the difference is too great to admit of comparison), we find that the number of lectures required by each stand as follows:—For the College of Surgeons, 840; for the Apothecaries' Hall (including 30 clinical lectures), 1130; for the two together, 1350; and these must all be attended in two years and a half. But for the University there are necessary 1300, including clinical lectures, which we reckon at 240—that is, 40 on each subject in each year; or, considering (as the students will feel, and as the Apothecaries' Hall admit) an examination to be equal to a lecture, the whole number will be 1512, to be attended in three years. Surely the Medical Faculty never thus reckoned up the demands they are about to make on the time and patience of well-educated young men, whom they command to be at the same time occupied in dissecting, and in attending to the practice of an hospital, and all that appertains to the practical study of medicine—1512 hours!! It is truly exorbitant.

The Faculty seem to have striven to be eclectic; they have seized with one hand the sublime, and with the other the ridiculous, but they have inclosed within their grasp none of the middle and substantial common sense of the matter. They have copied, on the one hand, the example of Oxford and Cam-

bridge in demanding a previous liberal education, to fit the mind for the active study of medicine; and, on the other, they have imitated the example of the Apothecaries' Hall, in requiring the student's time to be spent in passive attendance upon a vast number of lectures. They have even exaggerated the systems of both establishments, and the result is, as might have been expected—a system inferior to either of them. Both of the systems which that of the new University seems intended to embody, are at least founded on plausible grounds, and are adapted each, in some measure, for the class for which it is intended. Oxford and Cambridge, for instance, profess, and with much justice, to teach men not so much to be, as how to become physicians: they teach them science generally, and leave them to apply their knowledge to medicine; and the best proof of the excellence of their system is in the result, that the Doctors of Medicine of Cambridge and Oxford are the very men whom the London University is anxious that its Doctors should equal, and who have raised the character of the physician to “the estimation which in this country it has always maintained.” The Apothecaries' Company, on the other hand, assuming with less justice that students are unable to study by themselves, bind them to a passive course of attendance upon lectures: they require no previous knowledge, but a profuse study of medicine and every thing relating to it. The London University first requires its graduates to prove their capability of studying by themselves (for their preliminary education, having no regard whatever to medicine, can serve no other purpose), and then, as if dealing with so many children, marks out a fixed and unalterable plan, according to which they must be taught their profession. To a

youth who receives his first introduction to science when he begins to study medicine, it may be necessary to fix a plan by which he may proceed over the unknown land, though we have no doubt it would be best to let him learn all the good practice that is possible, and no more science than is necessary; but surely one that is already accustomed to the language and pursuit of every science except medicine, may, when he goes in pursuit of medicine, be trusted alone. The present scheme would just treat the best graduates of Universities like the worst apothecaries' apprentices.

When we examine what the 1512 lectures are composed of, we find that the number required for each subject is, in every instance, less than the number required by either the College of Surgeons or the Apothecaries' Hall. But the great total is made up by the introduction of no less than five new courses—viz., comparative anatomy, general pathology, general therapeutics, hygiene, and practical chemistry (not to mention general anatomy and physiology). The addition of these to all those usually demanded would be only ridiculous, if the scheme did not include a cunning job, which it has been the interest of some of the Faculty to practise, and the misfortune of the others to overlook. It is impossible not to see in all this the anxiety to provide lectureships for five friends, and a monopoly of students for the Gower Street Hospital and School. It would be easier to name the five favourites than to imagine what other reason can be given for the introduction of these subjects as so many separate courses. No one has ever said a word in favour of the general therapeutics—perhaps because no one knows what they are; and those who have argued for general pathology have been clearly enough shewn to

be in error. And who, except the future Professor of it, can speak for hygiene, as a study separate from forensic medicine?

We think we can see the same favouritism for University College and its Hospital in some other of the regulations; as in this—that the pupil shall study “practical medicine and surgery, in an institution in which the treatment of patients is entrusted to the senior pupils, under the superintendence of the medical officers, during six months*.” Now it is well known that the governors of our large hospitals will not permit pupils to have in any way the charge of patients; for neither dressers nor clinical clerks can be said to treat the patients to whose cases they attend, and house surgeons and apothecaries are always qualified practitioners. But it is equally well known that the Governors of the Hospital in Gower Street†, if indeed there be any such persons, will permit any thing to be done there. The public exhibitions of Animal Magnetism in that Hospital sufficiently proved this, and give ample reason to believe that they will permit its character, as well as its name of *Valetudinarium*‡, to be buried and almost forgotten; or will leave their patients to the mercies of the senior pupils, who have promised to take degrees “over the way”; if by these or any other means they can attract students and their entrance fees.

But to return from the motives that suggested it, to the curriculum itself. We find that the attendance in hospital practice is increased from two years to three. This is an improvement, copied from the latest regulations of the College of Physicians; but we cannot imagine any objection

to a student's being brought at once to the practical study of disease: why should he not be much more in the wards than in the lecture-room throughout his whole period of education? The Faculty have clearly evidenced here, as in many other parts, the false and unpractical notions which they entertain. We pass over the “order of study,” which exhibits only some ingenuity in disposing of several unnecessary things, so as to make them look essential.

The previous examination, a kind of *little-go*, which is introduced for the first time in England, would prove, we think, (if ever put in practice) a very useful regulation. We suggested such a plan in our number for April 28th, and mentioned there the advantages which we believe would flow from it. The system of conducting the examination in part by written papers, (a plan lately adopted also by the Colleges of Physicians and Surgeons) is also a good system, which we have often recommended. We can say the same for the practical part of the examination in anatomy and chemistry, and the institution of examinations for honours. Indeed, in the greater part of that portion of the Report which relates to the examination, there is much that merits praise; and we only fear that no one will be found who will wade through so much that is bad, to test the excellence of the last act.

In the regulations for the degree of Doctor of Medicine, it is ordained that the candidate should write and defend a Thesis. Surely this might have been omitted; the faculty must know that it is everywhere abused, “*usque ad absurdum*,” that a Thesis and defence, enough to satisfy any University from Oxford to Erlangen, may be, and are, almost universally bought for a few shillings. In another part of these regulations, they certainly shew a practical knowledge of their subject.

* See Report, p. 170.

† We use this name not out of disrespect, but as its only stable appellation.

‡ The name given to the hospital on the tablet of brass placed beneath the foundation stone.

The candidate for the Doctor's degree, who is to have been five years in practice, (to be certified we suppose by the maker of the brass plate on his door) is not to be examined in anatomy or chemistry, or any of those subjects which they compel him to occupy and lose so much time upon during his education, but merely upon subjects immediately connected with his practice. Now the Faculty have drawn this up from their own lives; none knew better than themselves that five years after a man has left the schools he has forgotten all that is not really useful, and yet may be a much better practitioner than when he knew all that was practically useless. Why, then, did they not remember (we are sure they have been told often enough), that what a physician neither retains nor requires in his practice, is not worth learning in his pupillage? Instead of thinking and theorizing on what scheme might make a kind of Utopian physician, they should have taken the examples of the best physicians in the kingdom, and having discovered wherein their superiority lay, they would easily have found how they might make pupils imitate them; for they would have seen, that on a sound and liberal, but not too multifarious education, the best physicians have grafted a sound practical knowledge of their profession, cultivating the collateral sciences rather as amusements than as essentials, and in many cases entirely neglecting them. To produce a class like them, they should expunge not only the five supernumerary courses we have already alluded to, but at least five more, so as to leave none but chemistry*, anatomy and physiology, medicine and surgery.

We have not now space to consider the rest of the regulations at any length.

* The extent of this course is injudiciously reduced to 80 lectures!—Only think of adding a whole set of new subjects, and curtailing chemistry??

We will only remark *en passant*, that midwifery is treated with the same neglect as it is in all the other institutions. One short course of lectures is alone required, and not a word is said of any practical study of it. Candidates for M.B. are, indeed, to be examined in it, and Doctors or *their equivalents* may receive certificates of proficiency. Similar certificates may be had for surgery, which is rather a dirty way of giving a side-blow to the College of Surgeons, in return for which the College would do well to institute what its Council have often discussed, a board of examiners in midwifery, who might bestow true and very desirable diplomas.

We must not omit one other point in which the Faculty exhibit a practical knowledge of their business. The examiners they ordain "shall each receive * * * from the University chest," which probably means that they must see first how many pupils they have to examine; not being in a condition to maintain sinecurists.

On the whole, indeed, we cannot find sufficient reason to believe that if the system be rigidly adopted, examiners in medicine will ever be much needed. Indeed, the London University, as far as the scheme of its medical department is concerned, offers no advantage, but is fraught with many great inconveniences. Its enemies hope nothing more than that the Senate will act in accordance with the last report. We hope that they will learn in time to be wise, and have the scheme altered to its very foundation.

SIR HENRY HALFORD AND MR.
LOCKLEY.

WE have not hitherto noticed the circumstances connected with the death of the late Mr. Lockley, because we did not regard them as forming a strictly medical question; but as more than

one correspondent has attributed our silence to other motives, we feel called upon to state our opinion on the subject.

It may be remembered that when the President of the College of Physicians introduced Sir Charles Aldis at court we instantly directed attention to the proceeding, in terms of the strongest censure, because that was a public act. When Sir Henry Halford, travelling with his friend, left him in an apoplectic fit at a station-house, we thought, as all else—save one—must do, that it was a proceeding remarkable for the absence it displayed alike of common feeling and common discretion; we did not notice it, however, because we regarded it as a private affair between man and man.

But further, having thus freely expressed our opinion, we take leave to add, that the purposes this transaction has been made to serve, and the manner in which it has been trumpeted forth, commented upon, and kept before the public, have much less the appearance of a generous and virtuous indignation than of a rancorous spirit of hostility and persecution.

WESTMINSTER HOSPITAL.

CLINICAL LECTURE BY JNO. BURNE, M.D.

October 22nd, 1838.

Advantages of Clinical Instruction.—*Nephritis, Anasarca; commonly called Inflammatory Dropsy.*—*Albuminous Urine.*—*Tests.*

GENTLEMEN,—Clinical medicine, in which department of medical education you are now to be instructed, will afford you the opportunity of acquiring practical knowledge—the great end and aim of all your laborious studies. It is on this practical knowledge you will have to rely when you first encounter the responsible duties of your profession: it is on this, improved by your own experience, you will have to depend for the reputation which will be the measure of your success and advancement in after life.

A systematic course of lectures on medicine teaches you principles, and furnishes

you with an outline of general, and a description of special, pathology. Clinical medicine teaches you the practice; teaches you to apply and make use of the knowledge you have hitherto acquired.

An abstract knowledge of the powers and virtues of remedies and of the long catalogue of diseases incident to the human frame, will serve you but little at the bed-side, until you have yourself seen these remedies applied and these diseases in actual existence; until, indeed, you have closely followed a course of clinical instruction. “Fit fabricando faber,” experience teaches. A person may be highly accomplished in the science of music, and yet be unable to play on a single instrument. So may he be deeply versed in the science of mechanics, and yet handle with awkwardness a knife or a saw. It is your object to be the man of science, and the practical man too.

Experience in medicine is gained not only by actual practice on your own part, but by observing the practice of those already experienced. I know it is a prevailing opinion that a student treating cases himself profits more than by seeing the cases treated by others: but this I hold to be fallacious; for, in the one instance, he has to rely on his own resources, necessarily limited; in the other, he has displayed before him the resources of a mind enriched by long experience.

The fact is, that a student, having a case in charge, has his attention roused and fixed, and here lies the advantage; whereas, in following the practice of another, he is apt to look on with indifference. If he will but concentrate his attention and engage his mind actively in all that is passing before him, he will derive an advantage infinitely greater than any that can accrue from his own isolated and individual exertions. Andral collected the materials for his *Clinique Médicale*, and founded his own reputation, while following the practice of Lerménier.

Now, clinical medicine affords you opportunities of observing disease, of noting the effects of remedies, and of studying pathological anatomy. Hitherto knowledge has been presented to you in the abstract; now it will be presented to you in reality. You will no longer have to imagine what disease is, but will see it in actual existence. “Homines amplius oculis quam auribus credunt: longum est iter per præcepta, breve et efficax per exempla.”

In your study of disease at the bed-side, let me recommend you to avail yourselves of every occasion to educate, and so to improve the senses of touch, sight, and hearing. It is not every one (said a lady to me) who can feel a pulse. And why?

Because they have not educated the touch. How often do we see, in the exploration of the abdomen, one person distinguish a tumor deeply seated, which another will pass over! So of hearing. A novice in auscultation will find all confused and unintelligible when he first listens to the pathological phenomena of respiration; but, by perseverance, by educating the ear, he will in time discriminate every sound with nicety and correctness. So of sight. One person will discover at a glance a difference of motion and a want of symmetry in the sides of the thorax, which may escape the observation of another. The great point is, to acquire the habit and power of fixing the attention; and then you will analyze and comprehend what you see and hear and feel. To profit much from attending your clinical instructor round the wards, your mind should be in full activity, awake and attentive to all that passes before you; for merely to walk the hospital is to spend hours idly, which you may flatter yourselves are spent with a praiseworthy regularity.

In the practical study of disease it is essential to observe symptoms *singly*, and in the *aggregate*; singly, that you may familiarize yourselves with the different kinds of pain, the different aspect of the countenance, posture of the body, &c.; in the aggregate, that you may learn to determine and recognise special disease, for every disease is indicated by a certain set of signs co existing, so that if any of the signs, which in the aggregate constitute any particular disease, are wanting, be assured that disease is not present. In this way you will perfect your means of diagnosis; that is, of distinguishing one disease from another.

In noting the doses and effects of remedies, and the circumstances which determine their administration, you will gain knowledge for yourselves instead of receiving it second-hand; and here you cannot be too precise in your observation; for depend on it, when you come to practise for yourselves, you will too often have to regret that you do not know the exact dose and the exact period in and at which some particular remedy was advantageously employed in some particular disease. How often has it occurred to me to ask a student the composition perhaps of a draught that he has seen prescribed twenty times with marked success, and find him at a loss for an answer, simply for the want of a precise and analytic attention.

By the dissection of the bodies of those who have sunk under disease, you will enjoy opportunities of verifying or disproving the opinions of your teacher, or those you may have formed for yourselves, and

of putting to the test of experience the doctrines you have been taught in the lectures on medicine. You will, besides, familiarize yourselves with morbid appearances, with the evidences of dissection, and thus perfect your knowledge of pathological anatomy. And having watched a case through its whole course, and having examined, after death, the morbid appearances, you will be able to compare the symptoms with such appearances, and the results with the opinions of the case entertained during life; and, in this manner, accomplish yourselves in diagnosis, prognosis, and means of cure, and fit yourselves for the actual practice in which it is your anxiety and your ambition soon to be engaged.

CASE XVI.—*Nephritis—Anasarca.*

The case I am now about to introduce to you and to comment upon is that of Richard Wood, aged 32, who was admitted on the 28th of September, 1838.

About the beginning of August he fell into the Thames, and allowed his clothes to dry on his back. In a fortnight afterwards he got wet again, and experienced a chill and shivering in the evening, followed by slight general indisposition. A week after this second getting wet, viz. about the 20th of August, he was attacked with pain deep-seated in the loins, and the urine became of a dark brown red colour. He experienced no further indisposition till the 14th of September, when he began to swell, first about the throat and head, then in the lower extremities; and on the 15th he was in a state of anasarca in a slight degree over all the body.

When admitted (September the 28th) he was affected with general anasarca, and great fulness about the epigastrium, increasing the size of his waist; the appetite and bodily health pretty good, the bowels regular, the pulse rather frequent and of good strength; the urine dark brown red, albuminous, and acid.

Sanguis e brachio ad $\frac{3}{4}$ x. detrahatur.

R. Elaterii gr. ss. ft. Pilula alternis auroris devoranda.

29th.—The blood free from buff, the crassamentum firm, the serum pale. He felt lighter and freer after the blood-letting.

Oct. 2d.—The elaterium purged him violently, to the extent of from eight to fourteen dejections, which were copious and watery.

The anasarca diminished immediately, and on the 5th was quite gone; he appearing not half the size he was when admitted seven days ago. The urine not improved.

R. Olei Tigli $\frac{f3}{j}$; Sp. Rectificati, $\frac{f3xj}{j}$.

m ft. Embrocatio, regioni renum omni nocti infundenda. Perstet.

21st.—He has continued the claterium, which has operated as before: he remains entirely free from dropsical effusion, and has no pain or complaint, except feeling a little weak from the purging. The urine remains of a ruddy brownish colour, though less deep than at the last report; it is natural in quantity and acid, but still very albuminous. The skin natural; and a good eruption has been produced by the embrocation. His appetite became so keen under the use of the claterium, that I was obliged to allow him full diet on the 8th ult.

Such is the case of Richard Wood.

What, then, is the disease? Dropsy unquestionably, of the kind usually called "inflammatory," in which blood-letting has been recommended by Dr. Blackall, on the ground of a supposed inflammatory condition of the system.

If this dropsy depended simply on an inflammatory condition of the system; and if, by antiphlogistic measures, as blood-letting, the dropsy was got rid of, the patient would be cured. But is this the case? Is this patient, Richard Wood, cured, now that the dropsy is entirely removed? No. And yet if you question him he says that he has no ailment remaining—that he feels quite well; which is borne out by his looks and buoyant spirits. But inspect the urine, and you will find it still albuminous, shewing that the functions of the kidneys is not restored to its healthy state; and experience has taught me that as long as there remains a trace of albumen in the urine, so long is it certain that the dropsy will return, if treatment is discontinued, and the patient allowed to resume his usual avocations and habits. This dropsy, then, did not depend simply on an inflammatory condition of the system.

The cause to which it must really be ascribed is a pathological congestion, an inflammation of the kidneys; as will be manifest by tracing the history of the case. The patient was exposed to an accidental exciting cause, the getting wet; which was followed by chills and rigors; then again by local pain referred to the loins, and general indisposition or febrile movement, together with a most serious and unusual derangement in the functions of the kidneys, as evidenced by the presence of albumen in the urine. Here you have a collection of symptoms indicative of an internal organic inflammation: the pain and lesion of function pointing distinctly to the kidneys as the seat. In this drawing you see represented the appearance of the kidneys in this state of inflammation.

The time which elapsed between the date of the accidental exciting cause and the supervention of the dropsy, was in this case unusually great—at least four weeks; the more common interval being from two to eight or ten days.

An accidental hyperemia or congestion of the kidneys, with albuminous urine, is by no means an uncommon occurrence: and often subsides in a few days without any disastrous consequence. This happened in the young man, Dodd, who was in the hospital some time since with valvular disease of the heart. He was suddenly attacked with feverishness, and as suddenly his urine became loaded with albumen; some blood had actually passed, the red particles of which were precipitated. He had had, as he told us, several of these attacks before, which had passed over in three or four days, the urine having recovered its natural characters. The same thing happened in the present instance; the feverishness abated about the fourth day, and the albumen and blood disappeared from the urine: no signs of dropsy manifested themselves. This, therefore, was a simple determination of blood to the kidneys, which subsided without passing into inflammation. The urine was precisely similar to the urine of patients in the first stage of the nephritis which leads to dropsy; and had the congestion of the kidneys persisted, a pathological action or inflammation would have ensued, and dropsy sooner or later supervened.

Albumen alone is not then pathognomonic or decisive of inflammation or disease of the kidneys; but co-existing with anasarca it is decisive.

The treatment of this case was conducted on the principle of subduing and eradicating an inflammation of the kidneys, which had already become chronic, it having existed, according to the history of the patient, already five weeks. Blood, therefore, was abstracted to the moderate extent of only ten ounces; for I had found by experience that larger blood-lettings, at so late a period of the disease, weakened the patients very much, without producing any proportionate good effect upon the condition of the kidneys. The claterium was administered not merely to get rid of the anasarcaous infiltration, but to excite a powerful determination to the mucous membrane of the intestinal canal, and so to relieve the kidneys; and with the same view was prescribed the croton oil embrocation, which has excited a high degree of counter-irritation on the surface of the body, in the region of the affected organs.

There is yet much to be accomplished in the case under consideration; for we must

not consider this patient cured until the albumen disappears from the urine. On most occasions I have found it impossible to keep the patients under treatment after they have become as well as Richard Wood is at the present time; they feel no ailment remaining, and, in spite of remonstrances, they leave the hospital and return to their former occupations and habits. The consequence is, that many of them return after a few weeks or months in a worse state of dropsy than before; others I never afterwards hear of.

Tests.—The most convenient and satisfactory tests for albuminous urine are *heat* and *nitric acid*. If both these agents give evidence of albumen, you may safely conclude that it is present in the urine. Other tests must be used with precaution, as they may lead to erroneous conclusions, on account of the number of the natural constituent principles of healthy urine, some of which may be decomposed by the tests, and yield a precipitate that may be mistaken for albumen. An error of this description occurred to myself. A lady consulted me on account of some puffy swellings about the ankles, and under the eyes, which were indeed œdematous. I examined the urine, and having a solution of the bichloride of mercury at hand, I made use of it as a test. Immediately some of this solution was added to the urine a dense white opaque cloud and precipitate were produced, which led me to conclude that the urine was albuminous, and the kidneys probably diseased. Next day, however, in observing the urine, I found it bright and clear instead of dingy and opalescent, as albuminous urine generally is; and having heated some in a spoon, no coagulation took place. The urine, in fact, was not albuminous. The bichloride in the previous experiment had been decomposed, and a lithate of mercury precipitated, which so resembled the precipitate of albumen as to be readily mistaken for it. I find that this occurs particularly when there is an excess of lithic acid in the urine. I have here a specimen of this kind of urine, to which, if I add a solution of the bichloride of mercury, an abundant white precipitate will be formed; as you see. The bichloride of mercury, then, should not be relied on as a test for albumen in the urine.

PHYSICAL SOCIETY, GUY'S HOSPITAL.

November 3rd, 1838.

DR. BABINGTON IN THE CHAIR.

DR. BARLOW read a paper containing some observations on the present state of

humoral pathology. Having taken a brief historical review of the opinions of more ancient writers, he proceeded to examine the state of the question at the present day. "If," said he, "we turn our attention to the present state of our knowledge of the pathology of the fluids or humours of the body, and inquire how far changes in these are to be regarded as primary causes of disease—when they constitute links, as it were, in the chain of causation, although primarily induced by some morbid action of the solid structures—and when they are to be regarded merely as adventitious coincidences—we shall, I think, not only find that one at least of the fluid components of the animal frame may be considered to be sometimes primarily affected as well as any other organ of the body, but also that all are subject to changes which, although induced in the first place by some structural or functional lesion of a solid organ, may become in their turn the immediate causes of more remote and more extensive disease," &c. The doctor proceeded to illustrate these positions by arguments, and reference to several forms of disease; for example, where the blood was obviously deranged. Thus in one class of cases there appeared to be an alteration of the proportions of the natural components of that fluid, as in chlorosis, anæmia, rheumatism, and the like; and in another, products had been detected there which did not naturally exist in it; as, for instance, bile in jaundice, sugar in diabetes, and urea in that form of dropsy associated with albuminous urine and diseased kidney, described by Dr. Bright. He concluded as follows:—"I am aware that many diseased conditions of the blood have been entirely overlooked in this hasty summary, my object having been rather to point out the application of many facts generally known, than to announce new ones which might be questioned. I trust, however, that I have said enough to shew that the blood is as liable to disease as the liver, the lungs, the kidneys, or any solid organ of the body; and that its diseases involve the most serious consequences. I would also suggest, that through the medium of the blood we may hope to exercise no inconsiderable control over diseased action in other parts; and though I should be unwilling to declare myself the advocate of an exclusive humoralism, I do not hesitate to say that an exclusive solidism is equally absurd in theory, and equally pernicious in practice. 'The humoral pathology,' said Bichat, 'has no doubt been carried too far, but it is founded on truth, and in a great many cases we must allow that all should be referred to morbid humours.'"

Dr. Addison said it was the universally accepted opinion of the present day, that the circulating fluid of the body might become contaminated, and produce symptoms of derangement of the system; but this contamination was in his opinion a secondary result, brought about by the agency of the nervous system. The general question of humoral pathology, in reference to the blood, resolved itself into three parts. 1st, the changes produced in the blood; 2nd, the secondary effects thereby resulting; and 3rd, the remedial measures requisite in such cases. These were matters chiefly of chemical inquiry, and it would confer a great benefit upon science if chemists would direct their attention to the innumerable ramifications of the subject. But with regard to the secondary effects of diseased blood he would remark, that he had often in practice been struck with the very trifling derangement of the general system, in cases where that fluid was obviously and strikingly contaminated, *e. g.* jaundice. In the simple forms of this complaint, the constitutional disturbance was usually so inconsiderable, that the patient is himself often not aware of his condition until it has first been remarked by those about him. When jaundice, indeed, is associated with organic disease, as enlargement of the pancreas, &c. obstructing the gall ducts, undoubtedly bad symptoms existed—but these are the exceptions; and even here, perhaps, the general derangement is more properly to be attributed to the interruption of the natural functions of the organs, than to any contamination of the circulating fluid.

Renal dropsy at first sight appeared to countenance the views of the humoral pathologists, for here the blood seemed to be first in the chain of derangement; but reflection and closer investigation had led him to remark that the phenomena of this complaint closely resembled those of a poison operating on the nervous system, through the medium of the blood. But renal dropsy presents many anomalies; for although chemists had detected urea in the blood, they had likewise asserted that the injection of urea into the blood of animals was not followed by evil consequences. Also, inflammation of the kidneys, without coagulable urine, and with little interruption in the quantity of their secretion, will often produce as urgent head symptoms as could be observed in renal dropsy; but these were anomalies which the Doctor would not attempt to reconcile.

Dr. Golding Bird said that a proper acquaintance with the natural composition of the blood was essential, before its disordered state could be appreciated; in order

to arrive at this, a minute chemical analysis was not necessary; but if it be examined somewhat upon the plan laid down by Müller, *anatomically*, or rather *chemico-physiologically*, it will be found to consist of animal and earthy parts. The latter being the salts principally; the former being albumen under different forms; viz. 1st. The solid albumen, or fibrine, which spontaneously separates when the blood is drawn from the circulation, &c. 2d. Albumen, which remains dissolved in the serum, and is detected by heat, nitric acid, &c. 3d. Albumen in combination with colouring matter, constituting what has been termed hæmatosene. 4th. Albumen in combination with salts—a form which had been pointed out by Dr. Babington, the president of the evening. Now, in healthy blood, these maintain a general uniform ratio to each other, which becomes modified under various circumstances. Thus the more robust the individual, the greater the preponderance of the first form, or fibrin; if he debilitates from any cause, the second or serous form increases; and as debility progresses, this in its turn becomes weaker; so that at length little or no solid matter remains for the growth and reparation of the body. In inflammatory cases, the converse obtains, for wherever there is a tendency to the formation of new products, as in pregnancy, the fibrine or solid albumen increases, and is detected in greater abundance in the blood.

In jaundice he imagined two distinct conditions of blood to exist. In the more frequent form, or simple jaundice, where there is little constitutional disturbance, the fæces are clayey, and the aspect yellow; the peculiar colouring matter of the bile existed in that fluid, and was detected by means of muriatic acid; but in another class of cases, where constitutional symptoms ran high, where the aspect was ashy, the fæces superabundantly bilious, &c. the resin of the bile was taken up. This he suggested was the inflammatory and more dangerous form of jaundice. Dr. Bird made some further remarks on the state of the blood in chlorosis and in bronchitis, which our space will not permit us to dilate upon; he expressed his belief that the blood is often deranged in the body, and gives rise to severe symptoms; but he admitted that all this was secondary to some prior exciting cause, which occasions it to be contaminated.

Mr. Chapman thought the instance of rheumatism was explicable on Cullen's theory of spasm of the extreme vessels. A healthy man is exposed to cold; the capillaries contract; the blood is thrown back upon the heart; a reaction takes

place to the extremities; nature exceeds her salutary boundaries, and thus arises rheumatism. So, in the treatment, in the majority of cases early depletion and antiphlogism will cut short, or greatly alleviate the attack.

Dr. Ashwell agreed with the author that chlorosis and anæmia essentially depended on primary derangement of the blood. Close inquiry would often elicit, in cases of the former complaint, that the patient had been ailing and in bad health from infancy, as though there had been some defect of nutrition from the beginning. Children might be born with diseased blood inherited from the parent; and in infancy the nervous system was very liable to be disturbed.

Mr. Greenwood was glad to hear it admitted that an ordinary practical man might appreciate changes in the blood without reference to minute chemistry. He believed that, in anæmia and chlorosis, the blood was altered in quality rather than in quantity, and that all the symptoms resulted from this change in the blood; yet he felt that the nervous system must have been the cause of the deranged blood, for this could not have become diseased of its own accord. The difference between ancient and modern humoral pathology appeared to him to be this: the former surmised and supposed the existence of foreign materials in the blood in all cases of disease; the latter had proved that a change in the proportion of its natural principles was all that was necessary in many cases.

Dr. Guy believed that altered blood might circulate for a time with impunity, but that sooner or later bad effects must follow. So it might be with jaundice; if the bile remained long enough in the circulation it would be hurtful; but in the examples referred to by Dr. Addison, it passes off before it can do harm; and in like manner, the experiment of the injection of urea into the veins, quoted by that gentleman, did not seem to him to be analogous to the case of renal dropsy, where it existed as the result of diseased action; for in the former case the kidneys act, and remove it quickly from the circulation; in the latter it continues to circulate, and produces the mischief.

Dr. Addison had often seen chlorosis without change of colour in the cheek—before, in fact, the blood had become affected—exhibiting all the symptoms of chlorosis except the colour, and requiring the same plan of treatment for its cure; he therefore did not agree with Dr. Ashwell that the primary source of chlorosis was to be found in the blood.

Dr. Barlow spoke in reply, and said that the discussion to-night had confirmed

the opinion he had broached in his paper, that a great modification had taken place in the opinions of pathologists of the present day on the subject of humoral pathology.

Dr. Golding Bird said the ancients had surmised and guessed at much that the moderns had proved by experiment. He concluded by proposing a vote of thanks to Dr. Barlow for his paper; this was seconded by Dr. Addison, unanimously adopted, and the Society adjourned.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

November 13, 1838.

DR. BRIGHT, PRESIDENT, IN THE CHAIR.

THE first meeting of the season took place on Tuesday, November 13; Dr. Bright, president, in the chair; who congratulated the members on the prospects of the society, which he represented as very promising. Two papers were read to a crowded audience—the first by Mr. Arnott, the second by the learned president.

Case of malignant Disease occupying one half of the Tongue, treated by Ligature applied from beneath the Jaw. By JAMES M. ARNOTT, Surgeon to the Middlesex Hospital.

A YOUNG woman, aged 15, had a tumor the size of an egg occupying the right half of the tongue, and encroaching upon the base under the arch of the palate. It was firm and solid, of a purple colour, with a warty surface on some parts, a vesicular in others. A small blue swelling had existed and remained stationary on the part for nine years; but within the preceding three months had begun to enlarge, and had increased rapidly to its present formidable character. Various external applications and internal remedies had been tried without avail. The diseased mass could not have been included by ligature passed in the ordinary way through the mouth. An incision was made in the mesial line of the neck, immediately above the os hyoides; a double ligature was curved through the base of the tongue into the pharynx; one of these made to encircle the right half of the part behind the tumor, the other disposed longitudinally, so as to circumscribe it laterally; and the four ends of the two ligatures coming out at the wound in the neck, were then tied as tightly as possible; strangulation seemed effected; a portion of the tumor began to separate. But at the end of five days it was discovered that the sloughing was confined to the surface, and that the bulk of the tumor was still alive. A loop of wire was now passed through the mouth,

over the diseased half of the tongue, into the deep trench by which this was separated from the sound parts longitudinally and posteriorly; and this being tightened under the former, all vascular supply was cut off from below, and the part completely strangulated.

No dangerous symptoms attended the operation. The ulcerated surface left by the separation of the diseased mass healed kindly; and now, five months subsequently, there is no appearance of a recurrence of disease. The patient's deglutition is perfect. She speaks most intelligibly, with merely a lisp.

The author refers to a fatal case of this operation for cancer of the tongue by M. Jules Cloquet, and to another by M. Mirault, where ligatures, applied across the base only of the organ, were not followed by sloughing of the part, but where such benefit resulted from the diminution of the supply of blood that the appearance of disease disappeared, and the patient preserved her tongue.

Cases of Spasmodic Disease accompanying Affections of the Pericardium. By RICHARD BRIGHT, M.D. F.R.S. President.

The object of the paper was to illustrate, by recent original cases, certain rare and important complications of cardiac disease, viz. different forms of nervous irritation supervening upon pericarditis. The principal facts adduced by the author were comprised in the histories and post-mortem appearances of three remarkable cases, each of which presented peculiar nervous symptoms, to which, for the most part, might, the author conceived, be attributed the fatal terminations. In all these cases the nervous symptoms were spasmodic, being in one those of chorea, in a second of trismus and epilepsy, and in the third of hysteria.

The first case was that of a young man of 17, labouring under articular rheumatism, in whom, after some apparent amendment, peculiar spasmodic symptoms supervened, resembling accurately in every thing, except undue violence, the spasms of chorea; these were soon followed by general convulsions after some days of apparent improvement, to which delirium, requiring the straight waistcoat, was soon added, and he died about the sixteenth day after the commencement of the spasmodic symptoms.

The post-mortem appearances were those exclusively of heart disease, namely, adhesions of the pericardium to the heart, with appearances about the valves of the left side that might be referred to endocarditis in some measure.

The second case was that of a gentleman, who, after exposure to cold, was at-

tacked with articular rheumatism, and symptoms indicating rheumatic inflammation of the diaphragm, and pericardium probably also. To these symptoms, about the seventh day, were added difficulty of lying down, of breathing, and of swallowing; and on the ninth day of his illness the dysphagia amounted to trismus, and was accompanied by some opisthotonos; there were also some indications of pleuropneumonia in the left lung. Epileptic convulsions soon supervened, and he sank.

The post-mortem appearances were principally pleurisy in either side, with traces of intense pericardial inflammation along the course of the phrenic nerve; lymph on the diaphragm; and a circumscribed pleuritic effusion in the lower angle of the left chest.

After relating the particulars of these two cases, the author offered some observations and comments on them, pointing out particularly the probable sinister influence of the trismus, by preventing in the second case the administration of medicine, and of the occurrence of the intense pericarditic inflammation in the course of the phrenic nerve in the same case, as accounting for the nervous symptoms; insisting likewise on the value of mercury, with antimony and opium, in the treatment of such cases; and then referring to the literary history of the subject for the purpose of shewing that little attention had been paid to the fact of the occasional connexion of spasmodic symptoms with acute cardiac disease. In the course of the author's comments, short summary histories were given of five or six other cases, in which he had observed chorea in connexion with, and apparently arising out of pericarditic inflammation, all of which recovered, under remedies directed as against pericarditis.

The author then related his third case, authenticated by post-mortem particulars, being a case of hysteria connected with pericarditis. It was a case of a young lady of a phthisical family, and labouring under diffused glandular disease, but no strictly consumptive symptoms; who was at length attacked with dyspnoea in paroxysms, accompanied by shaking and apparently convulsive action of the diaphragm that threatened instant death, and resembled an aggravated form of hysterical convulsions. At the same time symptoms of omental tuberculation and other abdominal disease were observable, and she sank in about six weeks.

The principal morbid appearances were the following:—The heart and pericardium were firmly adherent in one mass to the sternum; the heart itself and its covering were glued together by yellow

matter of 1-4th of an inch in thickness; on the right side the phrenic nerve was involved in the diseased structure; the lymphatic glands were generally diseased, containing yellow deposits, as did also partially the surface of the right lung.

The author illustrated this case by some observations, for the purpose of shewing that the distressing symptoms were probably owing to the disease of the heart and pericardium; and the author concluded his paper by stating that he had since had another case, of apparently the same pathological conditions, which, however, having been prevented from post-mortem examination, he abstained from detailing.

UNIVERSITY EXAMINATIONS FOR DEGREES.

To the Editor of the Medical Gazette.

SIR,

IN the last number of your journal, you give the Cambridge examination for the degree of A.B., and contrast it with that proposed for the same degree in the new London University. It appears to me, sir, that the examination which ought to be compared with the projected London one, is that held at the University of Paris. I copy, for the information of your readers, the requirements for the *Baccalauréat en Lettres*. By these it will be seen that it is placed within the reach of young men who have had a liberal education, and who are aspiring to practise an honourable profession. Should the senate of the London University insist on their present requirements, and should they admit to the examination all comers, their diploma will, no doubt, be sought for; but it cannot and will not be by young men of seventeen, just entering on their medical studies. It will probably be desired by those who, from want of residence at the Universities at present granting degrees in arts, have no means of proving that they have studied the subjects embraced by the examination.

The regulations of the University of Paris are as follows:—

Age—no stipulation.

Certificate of preliminary studies, two years; the one of rhetoric, and the other of philosophy. The certificate will be received from a public school, from a father, an uncle, an elder brother, or from any any teacher.

A certificate of good morals, signed by the municipal authorities of the candidate's place of residence.

The examination embraces Greek and Latin authors, rhetoric, ancient and mo-

dern history, geography, philosophy, mathematics, and the physical sciences.

Should you consider this worthy of insertion, it is at your service.

I am, sir,

Your obedient servant,

JOHN CHARLES COOKE, M.D.

Coventry, Nov. 7, 1838.

Winds, S.W. and N.E.

Generally clear, except the morning of the 9th, afternoon of the 10th, and morning of the 11th; rain fell on the 9th and following day.

Rain fallen, .825 of an inch.

NOVEMBER METEORS.—An account of these will appear in our next.

CHARLES HENRY ADAMS.

NOTICE.

We have been unavoidably obliged to postpone Dr. Cape's letter, from an accidental miscalculation in regard to the length of some of the articles in the present number.

WILSON & SON, Printers, 57, Skinner-st., London.

LECTURES ON SURGERY,

DELIVERED AT ST. THOMAS'S
HOSPITAL,

BY THE LATE MR. CLINE;

With Notes.

LECTURE IX.

*Phimosis—Circumcision—Amputatio Penis—
Extraction of Stones from the Urethra—
Suppressions of Urine.*

Phimosis.—By this is meant such a diminution of the extremity of the prepuce, that the glans cannot be denuded, and which may arise either from natural smallness of the part, or a contraction having taken place in consequence of inflammation. When there is a natural phimosis, which is generally the case in children, it occasions an accumulation of the secretions from the sebaceous follicles, or glandulæ odoriferæ, so that a cheesy like substance is deposited on the inside under the prepuce. When collected in quantity in that part, it is apt to produce inflammation, in consequence of which the parts become excoeriated, and there is frequently a discharge similar to that from a gonorrhœa, and it has been mistaken for such. Patients who have a natural phimosis are subject to this, if they do not frequently syringe the matter out, and should have an operation performed for their relief. The smallness of the aperture is generally confined to the extremity: if, therefore, we divide it at the extremity, it will be often freed sufficiently to be drawn over the glans. This has frequently been done by slitting it up in its whole length laterally, for on the upper part is situated the vena tegumentorum, which usually furnishes a

troublesome hæmorrhage: being slit up on one side, causes it to hang off on the opposite, which is very inconvenient and troublesome; therefore it is better to make two incisions, one on each side, but only half the extent; which is more conveniently done by a curved knife than any other instrument, pointed with a small bit of wax at the extremity. This generally gives sufficient room for the prepuce to be drawn back over the glans penis: after being divided, a great deal of inflammation comes on in the part; when this inflammation continues for any length of time, it more frequently depends on the position in which the penis is kept, than on any other cause, namely, suffering it to hang down; on the contrary, if the penis is fastened to the abdomen, so as for the extremity to be the upper part, then the fluids pass down the cellular membrane towards the pubes, and the inflammation soon abates. It is a considerable length of time before the parts become so loose again as for the prepuce to be brought forward, which patients should be apprised of, otherwise they find they are not at first benefited by the operation, as they had expected. During the time of healing the wound, the divided parts should be carefully separated, otherwise union would take place, and no benefit arise. In those cases where phimosis arises from inflammation, and is not the natural form of the part, it mostly appears in venereal cases, and most commonly from chancres. These not only occasion a phimosis, but some adhesions between the internal surface of the prepuce and the glans; in this case, where there are chancres on the glans as well as prepuce, during the cure the granulations of one are shooting into the other, in which case the adhesions may be discovered by passing a probe between the two. Here the operation is not so simple as in the former case: we should examine with a probe all round to find where the adhe-

sions are situated, which should all be removed by the knife, the part drawn back, after making the incision as before, and lint introduced between, from day to day, till the wound has perfectly healed. Very frequently, in long-continued venereal cases, the prepuce becomes extraordinarily thickened: in such cases, if it was to be slit up on each side, throughout the whole extent, yet there would be such a mass of thickened integuments that it would never after fold back from off the glans penis: here it is necessary to remove the whole prepuce.

Circumcision.—In such cases, when you come to divide the prepuce, you have a difficulty of distinguishing where the glans is situated, as it cannot be denuded. The prepuce should be first slit up to the corona glandis, and when you have sufficiently exposed the glans, the prepuce should be removed. Those who have a natural phimosis are subject to paraphimosis, which is the prepuce being drawn back behind the corona glandis, and there tightly embracing the penis, is incapable of being brought forward again over the glans; consequently a considerable degree of inflammation and pain follow, and great inflammation of the penis; for the patient is in the same state as if a ligature had been made round the penis, a little above the glans. The circulation is obstructed, and it may be considered as in a state of strangulation. If this has happened it would be right to try fomentations; or what is still better, snow. If recent, you may sometimes successfully reduce it, by grasping the glans penis, pressing it for a time, by which you will empty it nearly of all its blood. You then take hold of the penis with the fingers of each hand, and apply the thumb on the glans, pressing it back, and drawing the prepuce forwards at the same time. But sometimes the prepuce is so tight that you cannot succeed in this way, when it will be necessary to divide the skin in any part where the stricture is the greatest. It is useless to divide the skin in any other part but where the groove is situated, that is, where the pressure is the tightest: with the point of a lancet or knife you make two or three incisions, about half an inch on each side. Nevertheless, from adhesions, it cannot always be brought forwards, which we need not be solicitous about, having freed the strictured part. These incisions free the skin from embracing the penis, when you reduce it the same as before. This I have known happen to children who have had a phimosis. There is a case mentioned of a boy getting the ring of a key over the penis, and its swelling out at the extremity, so as to become in the same state as in paraphimosis. In

such case you probably would succeed in removing it, as in removing a ring from the finger, when a good deal of swelling has taken place in the finger—by carrying a long piece of thread underneath the ring—the remainder you twist tightly round the finger, from the ring to the extremity; you then begin to untwist the thread from that end through the ring, by which means you will be gradually drawing the ring off.

Amputation penis.—This is sometimes necessary from cancerous affections of that part. Sometimes irregular excrescences arise on the surface of the penis, at first sight not unlike venereal warts, which, after a time, become hard and painful; these ulcerate and put on a cancerous appearance, which will go on till the penis is entirely destroyed. I have seen the penis, scrotum, and testes, destroyed by the progress of cancer in this way. To prevent the progress of this disease the penis should be removed. This is sometimes all that is necessary, preserving as much of the skin as possible. This may be done by a circular incision carried round the penis, (the skin being drawn back), and then through it. A profuse hæmorrhage immediately follows, for four branches of arteries are divided, going to the corpus spongiosum and corpora cavernosa; besides, all the cells are bleeding, so that it is a bleeding surface. There is generally a necessity for tying these small arteries, which may be done by drawing them out with a pair of forceps, using a single ligature to each; then the integuments should be drawn over the stump, and secured by sticking plaster, except the orifice, into which a bougie should be introduced. This is necessary even when the inflammation is removed, to prevent the orifice being inclosed; for in healing the parts are all drawn together, and the extremity of the urethra becomes proportionally contracted, which occasions the patient to void his urine with much difficulty, and to be long about it. The bougie should be passed in two or three inches down the urethra, and kept in till it has healed, and some time after, as there is a disposition to contraction in the cicatrix, which would diminish the orifice of the urethra.

Extraction of stones from the urethra.—Now and then a calculus passing from the bladder becomes lodged in the urethra, and so far fixed that, after having passed a certain extent, the force used in voiding the urine is incapable of expelling it. Calculi about the size of an olive stone, and frequently of that shape, are every now and then passing through the urethra. They will sometimes get into the urethra, and gradually pass a little further each time of

voiding the urine, till at last they escape; but every now and then they become fixed in some part of the passage which may be smaller than the rest. When retained for any time they go on increasing in size, and their removal is absolutely necessary. If it has not already produced a suppression of urine, that will probably follow from the increase of the stone. The manner of removing it will depend on its situation. If near the extremity of the penis, it may be drawn out commonly with a pair of small forceps passed down the urethra; if this is impracticable, we next should make an incision through the penis to remove it. When situated beyond the scrotum, between it and the glans, you take hold of the corpora cavernosa, and keep the stone fixed in its position; then with a common knife dissect upon it on the under side, making an incision the length of the stone; it may then be easily pressed out of the urethra: this wound generally unites by the first intention in two or three days. Some have said that the integuments should be drawn back at the time of making the incision, so that when returned to their natural situation the external opening might not correspond with the internal one. This is very improper in cases of this kind, for if the internal wound should not close immediately by the first intention, the urine will pass through the wound, and effuse itself in considerable quantities under the skin, which would produce great inflammation, and in some instances has caused gangrene and mortification. When the stone happens to be lodged in that part of the urethra where the scrotum is adhering between the ligamentum suspensorium and bulb, it will be a very unfavourable place for the operation, for to remove it the scrotum must be cut through, which will endanger the passage of urine into that part, and produce general inflammation of the cellular membrane, which we should avoid if possible. To do this, if we cannot get it forwards, we should by a catheter or some such instrument push it backward. If you get it towards the perineum, you may make an incision and remove it at that part. If so fixed or wedged in the part that it cannot be removed, an incision should be made upon it, the external opening opposed to the internal one, that if the urine does get into the cellular membrane, it may at once escape by the wound. If there is not a free discharge of urine by the wound, a flexible catheter, or a hollow bougie, should be introduced into the urethra, to prevent its effusion into the cellular membrane.

Sometimes the stone is situated in the membranous part of the urethra, remain-

ing there, and afterwards becoming very much enlarged. Mr. Warner gives a case of this kind in his Surgery. In such there is generally little obstruction, for there is usually a little groove on one side of the stone. When you pass an instrument down the urethra, you come at the stone long before you arrive at the bladder, and when large, you may easily feel the prominence *in perinao*; this serves to direct the operator. A free incision should be made *in perinao*, on the side of the raphe, as in lithotomy, carrying it between the bulb and crus, the whole length of the membranous part, and the stone then extracted with the forceps. Notwithstanding the considerable dilatation, an incontinency of urine does not follow; the membranous part gradually recovers its contractile power.

Suppressions of urine.*—This in men may arise from various causes, as inability of the bladder to contract when the functions of the nerves are interrupted, as is often the case in injuries of the spinal marrow; this is easily relieved by the introduction of the catheter, drawing off the water occasionally. Also, from a small calculus getting into the urethra, patients have a gradual contraction taking place, which becomes gradually smaller and smaller, till the urine comes to pass off in drops; at length the urine is not passed off so fast as secreted; this should necessarily be obviated by some operation: it happens mostly in neglected cases of strictures of the urethra. But another very common cause, which comes on suddenly, is a spasmodic contraction of the urethra, occurring frequently to those who have the canal in an irritable state. Those persons who have long continued gleet are more subject to it than others. I have known men who have long laboured under gleet during the discharge have had very frequent evacuations of urine, yet on a sudden were attacked with a suppression of urine; and not uncommonly these spasmodic contractions of the urethra precede a permanent stricture. In these cases the spasm may frequently be removed by proper treatment. Sometimes it is attended with inflammation of the part, when venesection will be necessary, also purgative elysters; but what usually gives more relief is forty or sixty drops of Tinct. Opii. in a clyster, which will frequently in a short time remove the spasmodic state of the urethra; but what is still more successful is putting the patient in a warm bath or semicupium. Bladders of warm water to the pubis and perineum will often answer the

* The term "suppression" has evidently been confounded with retention of urine in the following lecture.—C.

purpose, producing a general relaxation of every part of the body. Nauseating doses of the Tinct. Mart. have been useful. A strong tobacco clyster has succeeded, but the patient was unwilling to undergo a second trial, from its rough action producing nausea and syncope. Frequently in the course of half an hour the urine will be completely voided in a full stream. In those cases, when you are at first unable to pass any instrument, there being such a firm spasmodic contraction of the urethra, you are now and then able to succeed by the use of a bougie, introducing it very gradually. In these cases it should be passed down the urethra to that part which is in the state of spasm, and should be left for a few minutes until the irritation produced by its introduction goes off; the parts not being in that state of contraction as at first, you are now to attempt to pass it a little further; so repeating the attempt, you by degrees are enabled to get it into the bladder. If you succeed in this way with the bougie, it should remain till the patient has a strong effort to void his urine.

In all suppressions of urine there comes on at times involuntary efforts of the bladder to expel the urine: if the bougie is in the bladder at the time of this forcible contraction, the patient should be directed to withdraw it instantly. In some of these cases, when there is inflammation, a blister on the sacrum has been found successful, and would probably be more so if applied to the perineum. The blister is objected to by some on account of the stimulant effects of cantharides being supposed to exasperate the disease rather than remove it; however, it has been found very effectual from experience in some instances of this kind, when it has not even excited strangury. But not uncommonly, in suppressions of urine, every mode of treatment is of no effect, the water goes on accumulating, and the patient's life is in hazard. Sometimes the bladder has burst; more frequently it has gone on to mortification, from the vast pressure made on the part: to prevent which it has been judged necessary to evacuate the water, and to effect which there have been three ways proposed:—One is by making an opening through the pubes, making an incision there, laying bare the upper part of the bladder, and thrusting in a common trocar. In performing this operation there would be very little danger of wounding the peritoneum; but there are two inconveniences attending it—viz. the difficulty in retaining the canula after the bladder becomes contracted, which it does as the urine evacuates, and the canula slips out, when the urine, instead of passing through the wound, diffuses itself

into the cellular membrane, producing in that part very violent inflammation. If the canula is kept in, it must be by the extremity pressing against the bottom of the bladder, and this may produce inflammation. Mr. Sharpe gives an instance of a canula making its way through the bladder into the rectum. This operation, then, is at least very troublesome, if not very hazardous.

Another operation has been proposed, that of puncturing the perineum with a trocar, in which way the water will readily be evacuated; but the puncture made in that manner through parts of such considerable importance may do great mischief; it might pass through the prostate gland, by which it might divide one or both of the vasa deferentia, therefore producing the same effects as castrating the patient. But the operation may be performed in another way very safely, viz. by making an incision as in cutting for the stone, carrying it gradually downward to the prostate gland, laying it bare, and pressing it on one side; this gives you an opportunity of carrying the trocar by the side of the finger and prostate into the bladder; withdraw the trocar, and the urine will be discharged freely. I once performed this on a lunatic. The trocar I used was a short one, and the canula rather too short to be retained in the bladder. Though I could not get the canula in I introduced a probe, and the water continued draining till the bladder was empty. The wound was left to itself. In this case I had an opportunity of seeing how little pain is produced in maniacs to what there is in other people. During the whole time he did not complain of the least pain; even when I had occasion afterwards to touch the stricture with caustic from time to time, he did not express the least pain.

There has been another mode of operating proposed and strongly recommended by Petit, which is making an opening through the rectum into the bladder, for which he contrived a curved trocar with a cutting edge, and a canula corresponding. The manner in which he directs the operation to be performed, is to carry the finger of one hand into the rectum behind the prostate; you then carry this instrument by the side of the finger, and thrust it through into the bladder. Having withdrawn the trocar, the urine flows through the canula. At the side of the canula are perforations to secure it in the bladder till the strictures in the urethra are removed. This is dangerous on account of the situation of the vasa deferentia, as they gradually approach each other; and when near the prostate are almost in contact, so that they are in danger of being divided by

the trocar passing through the prostate. If to avoid the prostate, &c. you carry your instrument far backward, you are in danger of wounding the reflection of peritoneum ($1\frac{1}{2}$ inch above the prostate,) between the rectum and bladder, by which the urine would be effused in the cavity of the peritoneum, and produce general inflammation, consequently the patient would soon die. I have seen this operation performed several times, but in no instance did it succeed.

Women have spasmodic contractions of the meatus urinarius, producing suppression of urine, and the same may occur from *retroversio uteri*; in this case the bladder would be situated too high to operate per vaginam, hence above the pubis would be preferable; but in other cases, where the catheter cannot be passed, the operation per vaginam is to be preferred. In suppressions of urine in women a similar treatment will be required as in men, in every respect; but the operation in them must be varied, from the different form of parts. The operation is more favourable above the pubes than in men, the bladder being nearer the os pubis; other objections the same as in men. The best way of performing the operation in women would be through the vagina with a curved trocar.

Hydrocele is a collection of water within the scrotum; or, more accurately speaking, within the tunica vaginalis testis, there forming a tumor of considerable size; but besides the accumulation of water in this part, there are other species of hydrocele spoken of by authors. They make several varieties, as the hydrocele of the tunics, by which is meant nothing more than the anasarca state of these parts, when the tumor is not confined to one side of the scrotum, the whole scrotum being distended. We also find in books the hydrocele of the spermatic cord spoken of. As for the tunica vaginalis of the spermatic cord, we have no other membrane but the reflection of fascia going around it.

Besides, we have circumscribed cavities occasionally containing water, situated in parts about the spermatic cord; but then these are only to be considered as hydatids. Such hydatids may be formed within the tunica vaginalis and epididymis, or on the outside of the tunica vaginalis; or when there is an old hernial sac, which has become closed above, and whose cavity is open below, a collection of water may take place in that, and form a kind of hydrocele of the spermatic cord. The tumor here is affected by the abdominal muscles on the patient's coughing, but in a less degree than in hernia. There are varieties which are now and then taking place of these parts, which are very rare when compared with the hydroceles of the tunica vaginalis testis itself.

It may happen, from partial adhesions taking place in the tunica vaginalis, that water may be situated in more cavities than one. From hernia humoralis, a partial adhesion may take place; thus it may accumulate in two cavities, on which account the variety of the situation of the water not uncommonly renders the management of the hydrocele very troublesome. Therefore, before we proceed to the cure, we will point out the characteristic marks or appearances of this disease. Its progress is attended with little or no pain, though the enlargement is great; this increase is so very slow, that frequently it is unattended with pain. The tumor begins from below, and gradually extends upwards, generally uniformly round, and gradually as it enlarges takes on a pyramidal form, larger below than above; has a fluctuating feel extending from one part of the tumor to the other, and in some instances is transparent. However, this is a criterion which is very fallacious, as the tunica vaginalis is sometimes so thick that there is no transparency; and sometimes the fluid contained is so dark, from blood, that the tumor is quite opaque; therefore we should rather determine from the former appearances than this. It is distinguished from a hernia, by this last descending from above downwards, and also by the enlargement which takes place on coughing. A hydrocele also differs from a diseased testis, by being circular on its surface, or uniformly round, though this is not always the case. There is also the same uniformity in some diseased testes as in the hydrocele; also in some, the same softness of parts and fluctuating feel. In some cases these appearances are so similar, that you cannot distinguish which it is without making an opening, therefore it requires an operation merely of inquiry—a puncture to see if there is any fluid. There is one circumstance by which you are very fortunately enabled to judge when every other fails, viz., if a hydrocele, it is not so heavy as a diseased testis.

In recent cases, and in children, sometimes a solution of crude sal ammoniac and emetics have succeeded in curing it. If the patient is willing to have all that is necessary to be done in cases of this kind, you may proceed in such a manner with the operation as to go on with the radical cure, if it should be hydrocele; or to castrate the patient if a diseased testis. Hence it is sometimes necessary to apprise the patient that you will proceed according to circumstances.

The palliative cure consists in making a puncture into the tunica vaginalis and discharging the water, which may be speedily done with a small common trocar,

grasping the tumor in the hand, and making the puncture on the anterior and inferior part, as the testis is situated in the posterior part. Before you perform the operation you should ascertain the situation of the testis. You should make pressure on the part, and inquire of the patient whether he feels you squeezing the testis or not, by which you come at a knowledge where the testis is. But a common trocar penetrates with difficulty, therefore is a troublesome and painful instrument; a more convenient one is that which is flat; it penetrates more easily, having a sharp edge. Mr. Andr  e has contrived an instrument better than these—an elastic canula, composed of two pieces of steel.

But it may be very easily performed by a lancet and a probe, which gives less pain than a canula; having first bent it, it will not slip out, and the water trickles from the opening. The only inconvenience is, that if you do not carefully introduce the probe before you have withdrawn the lancet, you will not be able to introduce it at all. As the accumulation goes on rapidly in many cases, few patients are capable of going longer than twelve months without submitting to the same operation; therefore by far the greater number of patients would rather undergo the radical cure, which consists in producing an inflammation which shall entirely obliterate the cavity of the tunica vaginalis, and which may be variously effected; besides which there has been an operation for entirely removing the tunica vaginalis, called excision, which is done by laying bare the tunica vaginalis and cutting it all away; but this is extremely painful, the tunic being an exceedingly sensible part, and very large in size; also, after the operation, very severe symptoms come on, for the testis being so completely exposed, violent inflammation takes place in that part—so much that many have died. It was recommended by Douglas, and once by Mr. Pott, but is now generally laid aside. Another operation is, that of introducing a sponge tent into the tunica vaginalis, and obliterating the cavity by producing adhesions. This has two objections, viz., the difficulty of keeping a tent in the part (it has now and then slipped out, and the water become evacuated); and sometimes it produces inflammation only partially, and partial adhesions also, so that the disease afterwards returns in the remaining part of the cavity.

Setons have also been used, which may be considered as a double tent, strongly recommended by Mr. Pott, for which he contrived an instrument without danger of wounding the testis, introducing a skein of silk above and passing it below.

In some cases this has failed to cure, by producing only partial adhesions; the water escapes on the introducing of the seton; and the membrane falls into folds round the testis. The inflammation may be sufficient round the seton, but may not extend to distant folds, hence partial adhesions arise; of this we had an instance in a patient of Mr. Martin's, in this hospital, who performed the operation exactly as recommended by Mr. Pott; there was a collection of water laterally.

Another mode is by incision, which is by laying open the tunica vaginalis throughout its whole extent, from above downwards; thus general inflammation is excited throughout the whole membrane, and general adhesions are the consequence, and no danger of further accumulation. To prevent which, Mr. Hunter has proposed a mode of conducting the incision, which has been very successful, by introducing some extraneous body, and keeping it in till suppuration has come on, when it must granulate. When granulations are thus formed, the extraneous substance may be removed; then the parts will unite, and the cavity be obliterated; the most convenient substance is Farina Lini. Lint is apt to stick about the parts, and with difficulty afterwards removed. This last is a very certain mode of producing the cure, and has this advantage of being able to ascertain the state of the testis, whether there are such adhesions of it as are necessary to be removed. In the end of about five or six weeks the patient is generally cured.

Another mode is by caustic, which was the practice of this hospital for a great number of years. It has been particularly described by Mr. Else, and has some considerable advantages. A caustic case is made of the size of a sixpence, and an inch deep, to be filled with the common caustic, made with soap lees and quick lime; this may be left on till the next day. The pain it produces is inconsiderable in general; for when caustic is acting on a sound surface the pain is not very great, it acting very slowly, and goes off in about two hours. The success depends on laying on caustic enough, and letting it lie long enough. Under an idea that a small quantity would act equally with a large one, some have only acted upon the skin, and no further. This is a chemical process the caustic enters into, and combines with the animal substance; and you must have a sufficient quantity to extend its action down to the part. The caustic being removed on the next day, the part should be supported with a bag truss, with a little common dressings to the part. In a few days inflammation is excited in the tunica vaginalis, which is kept in a distended state by the water within. If great pain and tension, with colicky sensations and fever

arise, a very small puncture may be made through the eschar to discharge a little of the water. It would be improper to evacuate the whole, as it advantageously acts as an extraneous substance. Obliteration is here also effected by granulation, for the inflammation cannot produce adhesions in the sides of the tunica vaginalis, till at length it goes on to suppuration, when the eschar gradually ulcerating, separates from the tunica vaginalis, and the water is gradually discharged. Coagulable lymph is discharged in the form of sloughs; the internal surface goes on to granulate, and produces complete adhesions throughout every part, and the patient becomes perfectly cured. I have tried this myself, and seen it in Mr. Else's practice, and from what I have observed, think it the mildest mode of all others. There is generally less inflammation, though sufficient to produce a cure, and less symptomatic fever; therefore the patient gets well with less pain, and may generally go about his business, it being unnecessary for him to keep his bed. The only advantage of incision over the caustic is being able to see the state of the testis. In those cases of hydrocele, where there is any doubt of the state of the testis, I should prefer incision. I have known, when caustic has been applied, there has been no occasion to confine the patient one day. Every now and then the patient dies in consequence of the treatment, under every mode of cure. I knew of two who died under the use of caustics, but they seemed to be unfavourable constitutions. In one there was a disposition to apoplexy; in the other there was stone in the bladder. Also, there are many who would submit to caustic that would not submit to the knife.

entirely latent until an advanced period of life; sometimes, however, although not powerful enough to produce the disease in question, with all its characteristic attributes, it is nevertheless sufficiently strong to give rise to a certain degree of constitutional disturbance, and to occasion the appearance of one or several symptoms,—an offspring which the attentive observer may trace to the parent stock. Thus, the hereditary gouty diathesis often manifests itself by periodical derangements of the digestive organs, of the urinary and nervous systems, but no inflammation of the joints, without which it is erroneously thought that the disease cannot be gout. As gouty dyspepsia requires a very different treatment from the other forms of indigestion, it is a matter of primary importance that the practitioner should be able to recognize its true nature; but this he will not—he cannot do, unless he bears in mind the general principles I have spoken of, for gouty indigestion has no special characteristics; we can only distinguish it, when unaccompanied by affections of the joints, by the following indirect method:—If we find, *in a patient with hereditary claims to gout*, that indigestion has been frequent, but with intervals of good health between each attack,—if, too, the general state of the constitution seems to undergo a temporary improvement after each fit,—if the fit of indigestion often comes on without any apparent cause, and often cease unexpectedly, and, as it were, capriciously,—if the dyspepsia, while it lasts, produces a more than a proportionate degree of depression and nervous ailment,—if the urine exhibits, during its continuance, the well-known lateritious and pink sediments,—then the experienced physician will not fail to penetrate the obscurity in which the disease is enveloped, and will detect the workings of the hereditary gouty taint. In some persons this taint occasions a chronic and very troublesome indigestion, remarkable for distressing and almost irremediable flatulency; and this symptom alone may lead to the detection of the true nature of the disease. These observations will, I trust, prove useful, gentlemen, in enabling you to discover the origin of many anomalous cases of dyspepsia, which otherwise might have escaped detection; and here permit me to observe, that you will find nothing better calculated to command your patient's confidence than an occurrence such as this, which proves that you can name a disease from seeing but a few of its features: this betokens true accuracy of observation, and shews that practical knowledge may be applied with a degree of certainty little inferior to that which ensures credit to the anatomist when he ascertains the genus by examining a few bones of an animal whose entire skeleton cannot be obtained.

CLINICAL LECTURES ON MEDICINE,

Delivered at the Meath Hospital, Dublin,

Session 1837-8,

By PROFESSOR GRAVES.

LECTURE IV.

Subject of Hereditary Diseases continued—Remarkable Exceptions to the General Laws of their Transmission.—New method of treating certain cases of Epistaxis, and of preventing Chilblains; on the Modes of taking Exercise prescribed by Hippocrates; on the Healing of Ulcers by Scabbing.

GENTLEMEN,—We last spoke of hereditary diseases, especially gout. When a disposition to any malady is transmitted from parent to child, it frequently happens, as we have already seen, that this disposition remains

The laws which govern hereditary diseases and defects have not yet been sufficiently investigated. In some families the hereditary tendency is confined to the males; thus, I know a gentleman whose father and paternal uncles had ichthyosis, while his aunts were not so affected; the gentleman himself and some of his brothers, but none of his sisters, had the same malformation of the skin, which was again transmitted to his sons, but not to his daughters, *although, through one daughter, it descended to a grandson*. Dr. Copland mentions several examples of hereditary ichthyosis, in all of which it was confined to the males of a family; the brothers, Lambert, could trace it back through five generations, all the males of which were affected by it. Dr. Copland says "that it is very rarely observed in females." Dr. Ireland and I have seen it, however, in the females of a large and otherwise healthy family, whose features were very handsome, and complexion fair and beautiful; on the trunk and lower extremities the fish-skin existed to excess, so that of these ladies it literally might be said "*Desinit in piæm mulier formosa superne*." The skin of the children in this family did not begin to deviate from the natural structure until they were one year old. I know a family remarkable for the number of stutters it contains; this defect has existed in several successive generations, and is confined exclusively to the males. Though the females themselves never stutter, *yet the hereditary defect frequently reappears in the sons of the female branches*.

My friend Dr. Prichard, of Bristol, brings forward numerous examples proving that personal deformities are not unfrequently transmitted in families in the male line alone, or in the female alone. This has been exemplified in some cases where the males, for several generations, have had supernumerary fingers and toes, while none of the females were so affected. In the family of the porcupine man, described by Mr. Lawrence, all the females escaped, while the males were affected with the same cutaneous deformity.

These facts, gentlemen, lead to many interesting considerations. In the first place, it is well worthy of inquiry whether certain hereditary complaints do not affect one sex more than the other. It appears very probable that gout, for instance, descends more usually to the males than to the females. What law as to sex is observed by hereditary apoplexy, epilepsy, insanity, &c., future calculations must determine; certain it is, that in some families these diseases affect one sex more than the other,—an observation also applicable to phthisis. In the second place, we may remark, that mental capacity and moral qualities

occasionally observe the same laws; thus in some families activity of mind and talents, and in others certain virtues and vices, are confined chiefly to one sex. The same is true of likenesses, which are not necessarily handed down from parent to child in regular succession, but are sometimes subject to strange and unaccountable deviations; thus, it is common to find the son quite unlike the father, while the grandson presents a striking resemblance to the latter. In some families a likeness long lost suddenly reappears, to be again transmitted through several generations, when it once more vanishes, perhaps, but for a time. This fact I have observed in the picture galleries of old families; and I have felt no little interest in the observation, being convinced that what is true of likenesses, holds good with regard to diseases, and in this sense hereditary diseases are not only visited on the descendants by direct and uninterrupted transmission, easily traced, and necessarily attracting notice, but are handed down *per saltum* to distant generations. As the records of family complaints are usually very imperfect, and do not extend beyond two or three generations, it thus happens that diseases arising unexpectedly and simultaneously among many of the same stock, excite great surprise, for the sufferers are necessarily ignorant of the true source of the evils which beset them.

A man admitted in the beginning of November, presented some symptoms worthy of observation. He is about 45 years of age, very rubicund, and bears on his face an exuberant crop of well-earned pimples, whose natural red glow was dulled by a jaundiced hue of skin, indicating hepatic inflammation; he had also ascites and anasarca. When long-continued intemperance has broken down the constitution to the extent of producing hepatitis, jaundice, and ascites, the case is almost always hopeless; and such I pronounced his to be. His urine was at the time copious, pale, and albuminous. As the hepatic region was tender, and bowels confined, leeches and moderate aperients were used, but without any well-marked benefit. In this state he continued for some time, when suddenly his right hand and wrist were seized with violent gouty inflammation, which lasted for several weeks; from this time the hepatic inflammation (relieved, but not cured, by the means employed,) began to subside, the jaundice gradually disappeared, and the dropsical effusion was absorbed; in short, the man quite recovered in the course of a month,—a result, in my opinion, more to be attributed to the gouty inflammation of the joints than to the mild mercurial alteratives and local remedies employed. In a lecture formerly

published, I brought forward many examples of hepatic inflammation, and jaundice, coming on after the subsidence of arthritis. In the case before us the reverse was observed, for the gout followed and relieved the hepatitis. It is worth remarking that in this patient the attack of gout did not alter the urine, which continued to be copious, very pale, and deficient in the lithates,—a state of secretion very different from that usually observed during a paroxysm of gout.

I published, some years ago, a case of gout, accompanied by the same unusual symptoms. The patient, a gentleman subject to hereditary gout, presents also the additional anomaly of being attacked without any preliminary or concomitant dyspeptic symptoms. You are aware that many writers, and among the rest Dr. Copland and Dr. Macleod, dwell on the connexion between the gouty paroxysm, and the preceding dyspeptic symptoms; and I believe such is generally the rule. But the case to which I have just alluded, forms a very remarkable exception. This gentleman never labours under dyspeptic symptoms: he has neither acidity of stomach, nor flatulence, nor irregularity of bowels; he eats with an excellent appetite, and all his digestive functions proceed with the utmost harmony and regularity. Yet with all these advantages, and in the midst of blooming health, he is attacked with gouty paroxysms of the most violent description I have witnessed for many years; and what is equally remarkable, immediately before the gout localises itself in one of the extremities, he begins to pass urine in great abundance, of a pale colour, and quite free from the lithates and other deposits generally found in gouty urine. In fact, each fit of the gout is preceded and accompanied by a copious diuresis, in which five times the usual quantity of urine is passed; yet this gentleman derives almost immediate relief from the use of colchicum. I bring forward these cases to shew that a disease may exist and make its appearance in a very marked manner, without some of those symptoms which have been generally regarded, if not pathognomic, at least highly characteristic.

Indigestion and fever are the two states of the system in which the *lithates* are surest to appear in morbid abundance in the urine; in phthisis, although a patient has tubercular pneumonia and cavities, yet he will not have such urine unless he has hectic fever; *gouty attacks, when not preceded or accompanied by indigestion, and when unattended by fever*, may also fail to exhibit this urine, which consequently must not be considered as an essential, but only as an accidental symptom of gout.

In truth, gentlemen, we should be very

cautious in concluding that any one symptom (or rather the diseased state which gives rise to that symptom), is the cause of any other, in any given disease. Last winter I demonstrated that the anasarca of scarlatina does not depend on an inflammation connected with the efflorescence directly, as was usually supposed; and lately Mr. Colles and I had occasion to observe a lady, in whom jaundice was for a fortnight preceded by extreme itching of the skin: this proves that in jaundice the itching so frequently observed does not, as we have hitherto thought, depend on the bile deposited in the cutaneous tissue producing irritation, for here the itching preceded its deposition, or at least that of its colouring matter. Whether the acrid uncoloured principles were first deposited, and caused the itching before the deposition of the coloured particles made the jaundice apparent, must remain undetermined.

Permit me now, gentlemen, to direct your attention to the treatment of one form of bleeding from the nose. It not unfrequently happens that epistaxis constitutes the only ailment to which young persons are liable. I was consulted by two gentlemen within the last year, the one eighteen, the other twenty-eight years of age; they were both healthy in every other respect, and were both liable to bleeding from the nose, sometimes slight, sometimes copious, and then producing a degree of debility proportionate to the extent of the hæmorrhage; no disturbance of the digestive organs, of the heart, or of any viscous or function, was discoverable. There seemed to be but one defect in the constitution, scarcely explicable except on the somewhat mechanical hypothesis of a superabundance of blood, accompanied, perhaps, by a defect in the process of sanguification, whereby the blood's fluidity was altered. These ideas, borrowed from the now antiquated humoral pathology, served to indicate the method of treatment; and having no better guide to follow, I proceeded to put the plan thus suggested into execution: I accordingly advised my patients to live as dry as possible, or in other words, to restrict themselves to a minimum of drink. I directed them at the same time to take about half a drachm of dilute nitric acid daily, in divided doses. Although the reasoning which led to its adoption is scarcely tenable, yet the remarkable success of the treatment renders the result worth recording.

Hippocrates, in his curious and instructive work on diet, insists much on attention being paid to the quantity of drink allowed to patients in different diseases; it is singular, however, that he nowhere speaks of restricting the quantity of drink in cases of hæmorrhage.

Dr. Williams has lately recommended the dry treatment in catarrhal affections of the lungs attended with increased secretion. In young persons, when the sputa are abundant and easily gotten up, I can attest the efficacy of an almost total abstinence from drink. Not long ago, I was called to see a young lady, then on a visit in the house of the venerable Doctor Percival: she had been blistered, and had taken large quantities of squills, ipecacuanha, antimonial wine, and other expectorants, and had refrained from solid food, and indulged freely in demulcent ptisans, whey, tea, &c.; these means, with confinement to her room, had been continued about a week without the slightest benefit; the cough was incessant, depriving her altogether of sleep, and accompanied with much wheezing, and an abundant easy expectoration. All remedies were laid aside, an almost total abstinence from drink observed, and a strikingly rapid cure effected. In his work on Diet, Hippocrates gives some hints worth attending to; thus, in cases of constipation, he recommends a very varied diet, and he does so on good grounds, for a simple uniform diet is very apt to occasion constipation. Hippocrates lays much stress on different sorts of exercise in different states of health: riding, walking, running, wrestling, and rolling in the dust, &c. &c. are all examined at large, and recommended as suitable to particular conditions of the constitution; but running, riding, and walking, have also their specified varieties, not merely as to duration and velocity, but as to direction, for he carefully distinguishes locomotion according as it is continued in straight lines, in curves, or in greater or less circles, on flat, or on hilly ground, &c. &c. Exercise, in curves or in circles, appears to have been a favourite gymnastic remedy among the Greeks; it is now quite neglected, but perhaps undeservedly, for running, riding, or walking, in curves or circles, must bring a number of muscles into play, which are comparatively unemployed in rectilinear progression. The effects on the circulating and nervous systems must be likewise different, as is evident from the remarkable disturbance they undergo in the circular swing.

Perhaps the ancients were led by religious prejudices to attribute importance to curved and circular locomotion; even at the present day, a superior degree of sanctity is attached by certain nations to dances performed in circles. Mrs. Guthrie, writing from Eupatoria, remarks, "that she observed, at a Tartar mosque, a sort of holy wheel of whirling fanatics who kept flying round in a circle; the reverend father, who is placed in the centre of this curious

group, keeps spinning round till he turns his brain; and if he expires on the spot, which sometimes happens, he becomes a martyr saint of the Mahometan church."

It is worth noticing that Hippocrates recommends emetics in many chronic diseases; sometimes he directs them to be taken fasting, but usually after a full meal. Where indigestion is accompanied by headache, hemicrania, or brow-ache of an intermitting character, and in cases of dyspepsia where the tongue is broad and flat, and loaded with a white mucus, I have often imitated this practice, and made my patients eat a full meal of various substances, animal and vegetable, about half an hour before they take the emetic. The action of the medicine is not near so distressing, and it weakens the stomach much less than when taken fasting; its effects are also more striking, as it operates when the stomach, busily engaged in the process of digestion, is much more vascular than at other times, and is pouring forth its secretions in greater abundance.

Want of time has prevented me from laying before you, gentlemen, a continuous and detailed series of remarks upon someone or two important subjects; and consequently I have to-day been obliged to confine our attention to matters having no natural connexion, other than their being all of a practical nature; you will therefore, I trust, excuse the discursive and rambling scope of the present lecture, which is intended, like a frame, to hold and bind together sundry detached observations and remarks unworthy of a more detailed extension, but each deserving of at least a passing notice. Many persons, especially children, suffer much from chilblains, although this troublesome affection is often met with in the most healthy constitutions; yet, when the disease proceeds to a very great extent and degree of intensity, and occurs with violence, where the exciting cause, exposure to changes of temperature, has not been sudden or remarkable, we may then conclude that the sufferer's diathesis is decidedly scrofulous. This affection ought consequently to excite the attention of parents; for although in general it is merely a local ailment, yet in some children it indicates a general weakness of the constitution, and in all occasions much pain and annoyance. Sir Benjamin Brodie, by his admirable observations on the nature and cure of corns, published in the 17th volume of the *MEDICAL GAZETTE*, has shewn that affections, vulgarly reputed to be beneath the dignity of the medical profession, may afford a legitimate and ample field for our interference and assistance. In order to prevent the formation of chilblains, we must endeavour to protect the skin from the operation of the usual exciting cause of

the disease, and, in addition to cautioning the children to avoid exposing their hands or feet to rapid transitions from cold to heat, we should endeavour to render the skin capable of bearing moderate changes of temperature with impunity. This is best effected by washing the hands several times a day, at first with tepid and afterwards with cold water, mixed with a small porportion of spirits or of *Eau de Cologne*. Some parents do much injury by making their children wear flannel or woollen gloves, even in the house. Stimulating liquids, such as strong brine, have long been deservedly popular as preventatives of chilblains, and were recommended by Dioscorides; but none of those usually employed seem to me as efficacious as one which I was the first to use, viz. a solution of sulphate of copper in water, in the proportion of ten grains to the ounce. This must be diligently applied to affected or suspected parts of the skin with a camel's hair pencil; and as soon as the moisture dries off, the skin should be well smeared over with spermaceti ointment. The sulphate of copper lotion may be applied two or three evenings in succession, until it has produced a manifest effect on the skin; it must be then discontinued for a few nights—again, however, to be resumed as soon as the natural soft and tender texture of the skin seems about to return. You must be careful to enjoin the application of the spermaceti after each use of the lotion. By this simple plan, commenced early in winter, many children, previously martyrs to chilblains, have been completely protected. It is probable that the nitrate of silver would answer equally well, did it not discolour the skin in so unseemly a way.

A case, which deserves a brief notice, is that of a man in the chronic ward, who had old ill-conditioned ulcers on his thighs when admitted. These ulcers constantly discharged a quantity of foul sanies and unhealthy pus, and had remained open for several weeks. Mr. Parr applied an astringent lotion for some days; but as I thought I could cure him much more expeditiously, I ordered the lotion to be discontinued, and had the sores carefully dressed with the beaver or fur plucked from a hat. This was applied with the view of absorbing the discharge, and concreting, so as to form an artificial scab, which tends at once to protect the raw surface and check the formation of fresh matter. The result accorded with my anticipations in this instance, for the ulcers dried up and healed in a few days. I have followed this practice of producing an artificial scab for the last fourteen years, and I can recommend it strongly as applicable to the successful treatment of certain descriptions of chronic sores, and, indeed, of some recent wounds. Let us consider

for a moment how the consolidation of detached or divided parts is accomplished. In all your books on surgery you have an account given of a process which is termed adhesion, or adhesive inflammation, which in itself is looked upon as a kind of morbid process. It is unnecessary for me to enter into any argument to prove the fallacy of this notion, for Dr. Macartney has established the fact, that what has been termed adhesive inflammation exists no where except in the minds of surgical writers. He has shewn that healing is always most rapid and complete where no inflammation exists. He has proved that wounds in which no inflammatory disturbance is going on, heal most readily; that where there is a simple incised wound, or solution of continuity without laceration or bruising, and where proper care is taken to keep the parts in complete apposition, they unite, not by means of inflammation, but by a process of nutrition. When parts have been simply divided and then placed in apposition, fluids are poured out, which, coagulating, glue them together and accomplish their union; and there is just as much need of inflammation to complete this process as there is to produce the various parts of the foetus. It is not, therefore, necessary, for the cure of solutions of continuity, that any inflammation whatever should exist; and Dr. Macartney has conferred a great boon on society by shewing that, in such instances, the cure is established by a mere physiological process. We know that in numerous cases where a bullet or needle has been lodged in the flesh, it will go from one part of the body to another, causing solutions of continuity more or less extensive, all of which are repaired without any consequent inflammation. We know also that when a simple wound is closed by a clot of blood, it generally heals without inflammatory symptoms. It becomes, therefore, a question in what cases we can imitate this process of nature; and without entering further into theory, I may observe, that many chronic open sores which refuse to heal even when treated according to the most approved principles of surgery, by means calculated to reduce inflammation or promote granulation and cicatrization by bandages, adhesive plaister, ointments, caustic, &c., will often heal with great rapidity, by covering them with the fur of a beaver hat, carded cotton-wool, or any similar substance, and thus permitting the natural exudation to concrete and form an artificial scab. When this is effected, the edges of the ulcer approximate, and the sore cicatrizes. This process, however, proves successful only when you succeed in making the scab adhere as well over the whole surface as at the edges. But even in case it should fail, it will not do any harm, or

prevent you from trying other remedies. The cases in which it is most likely to prove unsuccessful is where there is a copious discharge of ichorous watery fluid, and where much irritation or inflammation exists. Where there is only a copious watery discharge, and no remarkable irritation present, you will often succeed by irritating or scratching the surface of the sore so as to make it bleed. The blood which exudes from the sore concretes readily, and a scab is formed in a very short space of time. By this plan I have repeatedly succeeded in making open sores and old buboes heal which had resisted other means. It is worthy of remark, that an analogous mode of treatment has been found very serviceable in the ulcers and wounds of trees; for the celebrated cement, invented by Dr. Forsyth, and the grafting wax of gardeners, both act on the principle of forming an artificial and intimately adhering scab. In recent wounds, even where considerable injury is inflicted, and where loss of substance has been caused, it is often quite possible to make use of this method; it has been supposed by most, if not by all writers, that bruised and injured parts require suppuration, first for their removal, and secondly for their renewal; but I deny this, and I could appeal to numerous cases where extensive loss of substance was replaced *under a scab* without suppuration, and where bruised parts were removed without suppuration.

The powers of the living tissues and vessels are quite adequate to the deposition of new and the absorption or removal of old matter, without the necessary intervention of suppuration. I have seen a great portion of the fleshy part of the tip of the finger nipped off by the clapping of a door in a steam carriage; I have dressed it with fur of hat; a scab has been formed, and under that scab the bruised parts have been absorbed, and the destroyed parts replaced without the formation of a drop of pus. *As inflammation is a mere accident, not necessarily connected with healing by the first intention, so is suppuration a mere accident, and is not essential to the replacement of loss of substance.*

Since the preceding lecture (which was delivered last year,) was corrected for the press, I have read Dr. Macartney's Treatise on Inflammation, one of the most original and important works that has issued of late years from the press. A perusal of what I have already published in the MEDICAL GAZETTE in June last, together with the contents of the present lecture, will shew that I have arrived at views in many respects similar to Dr. Macartney. His discovery of the fact that inflam-

mation is not necessary for the healing of wounds by the first intention, was the point from which I set out, and I was soon led by observation to the conclusion that suppuration and granulation are not necessary to, and essentially connected with, the repairs of accidents attended with loss of substance. To this Dr. Macartney's reasonings also tend. When illustrating this question at the Meath Hospital, I related a case of extensively broken knees in a horse of mine, which I succeeded, many years ago, in cicatrizing by scabbing, and without suppuration, to the great surprise of the veterinary surgeons.

ON SOME OF THE DISEASES OF THE PAPILLÆ OF THE CUTIS.

By JAMES PAGET, M.R.C.S.

Demonstrator of Morbid Anatomy, and Curator of the Museum, St. Bartholomew's Hospital.

THE papillæ of the cutis were discovered by Malpighi*, and first described by him in the same admirable papers which contain the first demonstrations of the true structure of the tongue, and of the chief seat of the colouring matter of the negro's skin. His description of the papillæ of the hand, though rough, is extremely accurate; but he rather assumed from analogy than actually proved their presence on the general surface of the body, where, indeed, they are in the healthy state so small and indistinct, that even since Albinus† lucid description, many anatomists, as Perrault and Cheselden‡, and, more lately, Gendrin§, have denied their existence.

They may be most distinctly seen on the palms and soles, after removing the thick epidermis by which they are covered, and on whose under surface they are exactly represented *in intaglio*, by the fossæ or sheaths into which they are received. They are arranged in arched and parallel lines, which form varied and somewhat intricate figures; each line being composed of a double row of densely set hair-like and very vascular processes, about half a line long, which stand rather obliquely on the

§ Histoire Anatomique des Inflammations, vol. i. p. 401.

surface of the cutis, like the pile of velvet. As one proceeds in the examination from the palm or sole towards the back of the hand or foot, the papillæ are found gradually less prominent, till they degenerate into minute tubercles or granules, which are set as densely as possible, but have no definite arrangement. The same condition prevails in the cutis covering the general surface of the body, which is therefore smooth, or but slightly granulated. In the depressed lines of its wrinkles, which are arranged either in an irregular net-work, or in the directions which will allow it to move in the freest possible manner on the subjacent parts, the cutis is denser and less vascular than elsewhere, and the papillæ are so little developed, that even Albinus* seems to doubt of their existence. But the following observations, though relating chiefly to the increase of size and other alterations to which they are subject, will probably be sufficient at the same time to prove their presence on every part of the cutis†.

The slightest degree of morbid enlargement of the papillæ is that which they present at some distance from chronic ulcers where the skin has a bright red or somewhat livid hue. In this condition, the papillæ on those parts of the body where, during health, they are least evident (as on the legs and thighs), become prominent and distinct. Their form is not altered; they are nearly cylindrical, and so closely set, that their summits form a surface as smooth as that of coarse velvet. In general, very little cuticle is secreted; only a thin pellicle covers the papillæ, and gives a fine polished aspect to the limb; the hairs fall off, and the orifices of their follicles are closed; the wrinkled lines, in which the healthy papillæ are so small, become obliterated, and the whole of the affected cutis presents a smooth, villous, and highly vascular structure, which looks moist, and just like the lining of the cheeks or lips. I imagine that this condition, which, according to Rayer‡, occurs in the squamous and

many other diseases of the skin, is but an extreme instance of the common turgescence of erythematous inflammation, in which their vessels becoming unusually distended with blood, the papillæ enlarge and swell without alteration of their form. It is a condition which may constantly be observed near chronic ulcers, though less evidently during life than after the skin has been minutely injected, because the secretion fills up the papillary interstices, and adheres closely among their prominences.

In a more advanced degree the papillæ become larger than they are on any part of the body during health, though still without any alteration from their natural form. In the preparation before me, which contains a portion of the skin from the neighbourhood of a chronic ulcer on the leg of an African, the papillæ are from half a line to a line and a half in length; their forms are between conical and cylindrical; their summits are rounded, and they are highly vascular. They are arranged very densely and irregularly; but from the excessive prominence of the larger of them, the surface appears coarsely granulated. In this case the ulcer was healing, and epidermis was secreted so thickly that it might easily have been separated into four layers, in the inferior of which the papillæ were represented as if the skin had been moulded into soft wax or plaster.

In cases of this kind there is more than a mere turgescence of the papillæ; the change seems to consist of a true but simple hypertrophy; for while their size is so much increased, their form and the characters of their tissue remain unaltered.

But in some other instances they undergo more remarkable changes, for with a great increase of size their summits become expanded; and as they are densely grouped around the margin of an old ulcer, some of them look like tufts of succulent leaflets, from half a line to three lines long, elevated on narrow pedicles, and considerably flattened. Others of the papillæ again, which have been longer diseased, are still larger and more swollen, rugged or filamentous on their surfaces, and collected into roundish, lobulated, and irregular masses, which seem made up of a number of soft and vascular tuber-

* Loc. cit. p. 64.

† Gurlt (Über die Haut des Menschen und des Haussangthiere, Müller's Archiv, 1835, p. 404) says they are apparently absent on the scalp; but though I have never seen them enlarged there, I should have no doubt of their presence, as well from its minutely granulated surface as from its extremely sensibility.

‡ Treatise on Diseases of the Skin, translated by Dr. Willis, p. 19, &c.

cles densely set on narrow pedicles. Masses of this kind, which may be split up into smaller portions like a cauliflower, form the majority of what are called fungous or warty granulations, which are remarkable for their irritable nature, which are extremely sensitive, and bleed profusely on the slightest injury, and which constantly discharge a large quantity of sanious purulent fluid. During life it is difficult to determine the composition of these growths, because the matter which they secrete accumulates in their interstices, and conceals their form, and because they seem to merge gradually into an exuberant mass of soft vascular granulations, which occupy the centre of the sore. Even after death it is scarcely possible to discern their origin in a diseased condition of the papillæ, except by tracing the gradations in the same limb, from the healthy papillæ on those parts of the surface which are at a distance from the disease, through the successive stages of alteration, first in their size and then in their form and tissue, to this in which all their characters are completely altered.

I find this disease of the papillæ connected with a peculiar and intractable form of ulceration, which occurs not unfrequently upon the shins. It is remarkable for the manner in which it spreads down to the periosteum of the tibia, and even into the bone itself, from whose medullary tissue, a soft, fungous, and irritable mass of vascular granulations arises, and occupies the centre of the sore*.

The papillæ undergo a very similar alteration in chimney-sweeper's cancer, which is the more interesting from the circumstance of that disease having its most usual origin in a *wart*, which probably consists, like the more common species of those growths, in a simple enlargement of the papillæ.

The warts here meant are not those flattened disks of thick cuticle, which are rather of the nature of corns, and which may be separated entire by maceration, leaving the subjacent cutis sound; but those excrescences from the cutis with pointed or granulated surfaces, "much like granulations that are healthy†," which are sensitive and

vascular, and which are so common about the hands, and organs of generation. Every one must have observed that when the top of such a wart is cut off, it bleeds from a number of minute points, and not from its whole surface, just as when one removes a thin slice from the ball of a finger, so as to cut off only the summits of the papillæ, as they lie each in its separate sheath of epidermis. Such warts, also, when they have been much irritated, and are about to fall off, split up into a number of pyramidal processes, enveloped in thick epidermal sheaths, which cover them as a glove covers the fingers. These are the enlarged papillæ of the cutis; and they exactly resemble the natural structure on the sole of the foot in the ostrieb*, in which the papillæ form long conical processes, with rounded apices inclosed in dense sheaths of epidermis, and blended towards the end of the toe, where the pressure is greatest, into one horny callous mass, like a huge wart. I have seen a warty excrescence, also, in which the papillæ are grown into hair-like processes, like the dermal villi of the whale*. They are more than half an inch long, and the mass has split up into dense tufts of vascular filaments.

In those large and complex masses of warts which are sometimes found about the anus, and the external organs of generation in those who have gonorrhœa, it is not easy at first sight to see that they have the same origin as the more simple kind; but after their removal, and when they have been immersed in alcohol, they may be split up into several portions, each of which will be found to consist of a group of enlarged and expanded papillæ, which are held together by sheaths, and an envelope of fine epidermis.

I suspect that the soot-wart, which forms the first stage of chimney-sweepers' cancer, as well as that warty growth in which cancer of the face and tongue commences, is of the same kind; but as yet I have not had an opportunity of dissecting either of them in their early stage. In some more ad-

* From its thus appearing sometimes to originate in disease of the bone or periosteum, this affection is generally described as a fungoid disease of the periosteum.

vanced cases of the chimney-sweeper's cancer, Mr. Lawrence* says:—"The affection consists not so much of a state of ulceration as in a warty or rather a fungoid excrescence of the affected part—what we should call a soft vascular kind of wart, which produces the same kind of offensive discharge as the ulcer." This condition very closely resembles that which I have described as the most advanced stage of the enlargement, with change of form in the papillæ, around the irritable and intractable ulcers of the legs. I have found it very marked round the margins of several deeply ulcerated cancerous sores on the scrotum, and around the cancerous ulceration of the wrist, which is described by Sir James Earle, in the third volume of his edition of Pott's Works. This hand (which is still preserved in our Museum†) was removed by Sir James from a gardener who was for some time in the habit of carrying a soot-bag on the corresponding arm, and it may be remembered that the whole course and character of the disease precisely resembled those of the chimney-sweeper's cancer of the scrotum. I find a large portion of the back of the hand and wrist occupied by a foul, ragged, and deep ulcer, around whose uneven border there are a number of elevated growths of various sizes, raised on narrow pedicles, and more or less densely grouped together, which, from their exact resemblance to the others already described, I have no doubt are enlarged and altered papillæ.

It would therefore seem highly probable that in all these cases of cancer of the skin, a single warty growth is first formed by the enlargement of a group of papillæ; and that when it is removed by ulceration, the papillæ around the margin of the ulcer become in their turn enlarged and expanded at their summits, and are successively removed in concentric circles, as the ulceration spreads. I may repeat, that the change from the natural form of the papillæ in the advanced stages of these diseases, is so great, that except after having traced them through their successive degrees of alteration, no one would imagine their origin. But the similarity of their forms in this extreme state of disease, and the very analogous

character of the spreading and seemingly incurable ulceration with which they are accompanied, can, I think, leave no doubt of the similar nature of the chimney-sweeper's cancer, the cancer of the skin of the face, the ulceration of the wrist described by Sir J. Earle, and the warty ulcers of the extremities, producing, and often *seeming* as if they depended on, disease of the periosteum and the bone; and I think that the expanded and flattened, or swollen, form of the papillæ around ulcers is peculiar to these which appear at present to be incurable; for as far as I have yet examined them, I have found the papillæ altered in size only around the more simple and curable forms of ulceration of the skin.

There is yet another class of cases, in which a somewhat similar change of structure occurs in the papillæ of the cutis, viz. in *nævi*. Most of that species of *nævus* which nosologists call *spilus*, and which appears to include all those which do not consist of the vascular tissue analogous to the erectile, present some characters which indicate an increased activity of the nutritive processes, in the portion of skin in which they are seated, such as a thickening of the cutis, by which the *nævus* is somewhat raised above the surrounding parts—a copious secretion of thick and dark epidermis—the growth of tough wiry hair—increased heat and sensibility, &c. Others, again, have a more or less coarsely granulated surface, from enlargement of the papillæ, which are, however, kept down nearly at the level of the skin. But there is a variety of *nævus* which consists entirely of an enlargement and alteration in form of the papillæ, in which they present some characters strikingly similar to those already described. This form has been well described by Rayer*, by the name of *verrucous nævus*; and Dr. Thomson gives a figure of it under the judicious title of *papillary nævus*†. I have seen two cases, but both after the removal of the disease from the body. One of these was removed by Mr. Abernethy, from the lower part of the back of a lady, and is preserved in our Museum. Mr. Lawrence‡, who assisted him in the operation, says that it was congenital,

† Series 7, No. 6.

was entirely confined to the tissue of the cutis, and had during life a bright red appearance. It is about a foot in length, and somewhat less in breadth. The other specimen was presented to the Museum by Mr. Taylor, of Clerkenwell. It was removed from over the sacrum and lower lumbar vertebrae of a woman who had been for some time a maniac. It was congenital, and had produced no inconvenience till, from her constantly lying on her back, it began to ulcerate. It decreased in size for some time before death, in coincidence with extreme general emaciation of the body. It is of about the same size as the other, but of a blackish-brown colour, from the secretion of a large quantity of very dark epidermis.

I was led to the true nature of the morbid change in these cases before reading the works just quoted, by the similarity which existed between the enlarged papillae in them, and in the cases of malignant ulceration already described. The surface of these naevi is of course sound, and covered by epidermis; but they are composed of a dense assemblage of simple and lobulated growths, from a line to half an inch, and in some cases even more, in length, which are elevated on narrow peduncles. Some have just the appearance of succulent leaflets, being flattened at their expanded summits. Others are knobbed or lobulated, or even slightly branched. They are composed of a dense, firm, homogeneous tissue, like that which is commonly found in hypertrophied skin, as in the lobulated tumors of the nose, some of the enlargements of the scrotum, &c. One artery enters the base of each papilla, and passing up its centre, gives off a branch to each of the lobules. In the last case mentioned, the secretion of epidermis was so excessive, that the interspaces of the enlarged papillae were filled with scales and detached portions of it.

As might be expected, the villi, or, as they ought to be called, the papillae, of some parts of the mucous membranes, are subject to similar affections. I have found those of the lining of the cheek remarkably enlarged over a naevus; those of the inside of the lips similarly altered in cancer, and in an exostosis of the upper jaw. Such changes occur also in the tongue and in the granular conjunctiva in purulent ophthalmia; and

Mr. Langstaff has a beautiful specimen of warty growth from the conjunctiva palpebrarum of an ox, which I have no doubt is of the same nature.

ON THE SKULL OF AN ANCIENT ROMAN,

AND SOME ANCIENT RELICS.

BY R. H. ALLNATT, A.M. M.D.

A MOST interesting discovery has just been made on the line of the Great Western Railway, at Shooter's Hill, in this county, which is a high and insulated portion of ground contiguous to the Berkshire Downs. As the excavators were proceeding with their labours, they lighted successively upon five human skeletons lying along the line of their operations; and as the bones were superficially embedded in the chalk and covered by dry sand, they were in a state of great preservation. These skeletons proved to be the remains of Roman soldiers who fell, in all probability, during the wars with the ancient Britons; for in and about the graves were found the spear heads, spurs, and battle-axes of British and Roman manufacture, urns of *terra cotta*, and a large quantity of coins of various Roman emperors. There was no mound, nor the usual series of small tumuli, to indicate the presence of these subterranean treasures.

I was fortunate in the opportunity of examining the majority of these reliques at my leisure. Two of the skulls are now lying before me, and as one of them presents some peculiarities of structure, and as the skull of a Roman does not occur to our observation every day, perhaps a cursory description of it may not prove unacceptable to your readers.

The bone is still hard and compact, and had undergone but little alteration of structure. Some of the animal matter has, however, disappeared, and its place been supplied by the carbonate of lime from the nidus in which it reposed, for it is adherent to the tongue, and effervesces strongly when acted upon by the mineral acids. The surface had a reticulated appearance, owing to the partial denudation of the external surface by ossiphagous insects.

The following are the dimensions of

the head and face of the more perfect skull; both crania, however, present nearly the same relative admeasurements:—

Dimensions of the Head and Face.

From the external angular processes of the superciliary ridges, $4\frac{1}{2}$ inches.

From the temporal ridges, across the inferior and more contracted portion of the os frontis, 5 inches.

From the temporal ridges, including the superior or more projecting part of the os frontis, $5\frac{1}{2}$ inches.

From the space between the superciliary edges immediately above the ossa nasi, to the tubercle of the occipital bone, $12\frac{1}{2}$ inches.

Lateral measurement of the depth of the skull from the middle of the sagittal suture (the original situation of the fontanelle) to the foramen magnum at the base, $9\frac{1}{2}$ inches.

Across the face, from ridge to ridge of the ossa malæ, 4 inches 7 lines.

Circumference of the whole head, measuring round the occiput and os frontis in the most developed parts, 21 inches.

Thus we see that the bones of the head and face are of dimensions exceedingly contracted, at least in comparison with those of a well-formed adult of the present day. Not being a disciple of Gall and Spurzheim, I leave the discovery of the moral habitudes of the owner to the lovers of the *science* of phrenology; but I may be permitted to remark that the ossa nasi of both skulls possess most extraordinary incurvations, which must have had the effect of subjecting the wearers, though Romans, to particularly “pug” noses, and we are all aware of the characters assigned by popular consent to nasal organs of this peculiar conformation.

The great departure from the regular structure, however, remains to be no-

ticed. The existing teeth of the upper jaw (the only ones, unfortunately, preserved) are eleven in number; five of the molares were lost during life, as the sockets, or alveolar processes, are consolidated by ossification. The crowns of the incisors stand prominently from the jaw, and are evidently not worn to any extent by attrition, but instead of presenting the usual wedge-shaped appearance (having the posterior and anterior surface meeting at a sharp angle), they are of an irregular solid oval form, strongly coated with enamel, and in every respect like the natural molares. The fangs are *single*, and of the usual long pyramidal form at their insertion in front of the maxilla. The bicuspidæ have also lost their identity, and partake of the same peculiarity; so that in fact the whole row presents the unusual appearance, along the entire line, of a set of sturdy and uniform molares.

The grinding surfaces of the teeth and bony palate—natural size.

That these teeth are perfectly natural and in their right situation I am quite convinced, as the fangs are single and the alveoli accurately correspond, and are adapted, to the peculiarities of the roots. I look upon it, moreover, as a purely *accidental* conformation, not presuming that the valiant inhabitants of the Eternal City so far departed from the universal system as to wear their molar teeth in the most conspicuous part of their maxillæ.

The vases I have mentioned above are evidently from the shape and diminutive size not cinerary, but were most probably the customary drinking vessels of the common Roman soldiers. A

a, ossa nasi from the Roman skull.
b, the same bones from a well-formed English skull.

notion prevailed with the ancients that the soul was the shadow of the living man, and that it was endowed, though imperfectly, with the faculties of the material body. Homer called these shadows *αεθρηα καρηνα*, weak bodies. According to Homer and Socrates the dead lived a kind of life resembling a dream, and was supposed to frequent the place where the body lay. Hence it was customary to place provisions near the spot. And Lucian says that ghosts derive their nourishment from libations and funeral sacrifices at tombs. From the prevalence of this superstition arose also the custom of burying provisions and drinking vessels in the graves of the common people.

Vase, or supposed drinking vessel of Terra Cotta, taken from the grave. Diameter $3\frac{1}{2}$ inches; depth 4 inches.

Thus I conceive the fact to be incontrovertibly proved, from the warlike weapons and other contemporary monuments of ancient art, which were interred with these bones, that they are the remains of Romans, and that these Romans were soldiers, who fell in the sanguinary wars with the Ancient Britons. The whole area of the hill was the scene of savage conflicts; for the graves (several of which contained considerable masses of charcoal) are scattered at the summit in great profusion.

The date of some of these reliques may be assigned to a period anterior, and of others subsequent, to the reigns of the Antonines, when cremation began by an imperial edict to be abolished; and this will account for the circumstance of charcoal existing in some of the graves, and of the entire unconsumed skeletons in others.

I forgot to state that a small copper coin fell from the interior of one of the skulls when raised by the workmen, which was probably the *sestertius* placed in the mouth of the deceased to pay the fare of the infernal ferryman of the river Styx.

Wallingford, Nov. 12th, 1833.

VACCINATION AND SMALL-POX.

To the Editor of the Medical Gazette.

SIR,

As, for some time past, the public attention has been excited by a great numerical increase of cases of small-pox, so I have observed, that through your journal the attention of the profession has been attracted by several writers on this subject, but more especially by the late interesting letters of Mr. Estlin, on a supply of vaccine virus, as obtained by him directly from the cow. It was not my intention to have obtruded my opinions at present, but seeing that an anticipation of them has in some measure taken place in your pages, I may be allowed, although only at the threshold of my experiments, to state the circumstances which led me to investigate the subject. In the months of March, April, and May, of the present year, small-pox prevailed in Ripon to an alarming and fatal extent. In several cases I found that although the child was vaccinated, and the vaccination proved by Bryee's test successfully, small-pox supervened—that not unfrequently, when under the influence of vaccination, the small-pox eruption made its appearance on the child, both diseases running their respective course together, the one not impeding the other—that many presenting upon their arms the genuine cellated scars, the result of early but successful vaccination, were also seized. I then took six persons from between the ages of 25 and 30, all of whom had been vaccinated in infancy; and revaccinating each of them, I found that they all took the disease in its regular form, the vesicles coming to maturity on the eighth day. From a very few cases, however, we ought to take care not too hastily to draw general conclusions. Thus, as opposed to these cases, I may mention that of a lady, who having had small-pox in infancy, permitted herself at the age of 30 to be vaccinated. The result was, that a genuine vaccine vesicle appeared at its height on the eighth day; and from it I vaccinated two children, and in both the operation took effect. Two other ladies of my acquaintance have had a second attack of regular small-pox. But these are the exceptions; a very few persons having what is called (from our ignorance) “a pre-

disposition" to a second attack of small-pox, whilst others cannot under any circumstances take the disease: thus I have inoculated myself over and over again, with variolous matter from the worst cases, without effect. When, however, we find that the result of many cases is in the greater part of them alike, we may then infer that some law exists causing a uniformity in the effects, and that that law may one day be discovered. We find *now* that vaccination does not afford, even to children, the benefits it once did; that in adults a second vaccination takes effect as it did in infancy; and that more originally vaccinated adults now contract the disease of small-pox than did some twenty years ago. Some have supposed that this arose from a wearing out from the system of the vaccine virus, and that a renewal of the vaccination was necessary after a certain number of years. Others, again, imagine that the virus itself has degenerated, and that its prophylactic virtues have been destroyed through so many systems. Both opinions appear to me to be correct in a great degree. No one doubts, for instance, that the matter was good and effective when Jenner, some forty-two years ago, began openly in London his experiments: the preservative effects continued for several years, but a time came, and still comes, when a second vaccination will take full effect; at which time, if the individual be exposed to variolous contagion, and if he be not revaccinated, the chances are that he takes the disease: but even revaccination, now-a-days, is not a certain preventive; the *stock* being bad, as innumerable instances prove, a revaccination with the old matter is too often but of little use. The period of deterioration or degeneration of the virus, will, by subsequent investigations, probably be found to be that very number of years at the expiration of which a renovation of new matter in the human system is called for. This is at present only thrown out as a supposition; formed, however, not without some reflection.

If such a removal of vaccine virus be necessary, it of course would be of high importance to be able, in any part of the world, to obtain a supply at pleasure. In the *Arch. Gén. de Méd.* for November 1831, Dr. Sunderland is said to have communicated an eruptive dis-

ease to a heifer, by clothing it with the coverlid of a variolous patient's bed, and to have successfully used the matter in engendering cow-pox in the human subject.

Before I read this, I had thought that, from the similarity of the diseases in many respects, it was not improbable that small-pox in the human subject might induce in the cow the disease called cow-pox; and this idea was favoured by the fact, that for several years back, when small-pox has been a disease of comparatively rare occurrence, few or no cases of the vaccine disease could be found in the cow. The inoculation of the teat of the cow could readily be accounted for, if we but believe the accounts given of small-pox previous to the discovery of Jenner. Not, however, content with the theory, I have gone on to experiment.

On Friday, the 13th of July, I commenced my experiments on a calf of a fortnight old. Having obtained matter from a boy of nine years of age, when the variolous eruption was at its height (ninth day), I carefully inoculated the calf on and around the teats. On Saturday, the 14th July, I took the same matter as used in the former experiment; and having made three cruciform incisions on the udder and teats of a milk cow, inserted well the matter. The incisions on the second day were puckered, and incrustated with a little dried blood, but in neither case was I able to discover any eruption; all symptoms of irritation died, and the scabs falling off left merely small smooth cicatrices. As yet I have not been more successful, although I have used both variolous matter and the vaccine.

I have openly communicated to many my opinions, expressing a desire that all who felt inclined would prosecute the subject, either to prove them correct, or disprove them by experiment. When at Newcastle, in September last, I mentioned my experiments to Mr. Fife, and it was from observing that another gentleman of that city had, through your pages, communicated somewhat similar views, that I have, at this early period of my experiments, offered to your readers these crude remarks.

I am, sir,

Your obedient servant,
JAMES INGLIS, M.D.

Ripon, Yorkshire,
Nov. 12, 1838.

ON SCURVY.

EXTRACT FROM THE

REPORT OF DR. MURRAY,

Principal Medical Officer at the Cape of Good Hope.

HAVING given the substance of the reports of the medical officers stationed on the Eastern frontier, respecting the scorbutic affection which prevailed there, detailing its symptoms and causes, with the means employed for its prevention and cure*, I shall next give some reports on this disease which I have received from medical officers and practitioners at Cape Town.

Report of Surgeon Mostyn, 27th Regiment.

Cape Town, June 1837.

The 27th regiment embarked in the troop ship Romney, at Cork, for the Cape, in May 1835, and arrived at Simon's Bay on the 20th August, and at Port Elizabeth on the 2d of September, from whence it marched to Graham's Town.

On the 25th October, the head-quarters of the regiment, with the flank companies, left the frontier for Cape Town; the other four companies remained until the end of March 1837, when they left, and arrived here on the 13th April.

During our passage from England the regiment was remarkably healthy, and no case of scurvy occurred, neither did the disease appear in it while I was on the frontier (up to the period of head-quarters leaving); but I understand that three or four cases occurred afterwards in the four companies that remained there, and that one man died of it in the hospital of the Cape Mounted Rifles, at Fort Beaufort. Up to the present period, I have only admitted one case of a scorbutic nature among the men of the regiment stationed at Cape Town, and the following is an outline of its history and treatment:—

Private Arthur Loughran, 27th regiment, age thirty-four years, admitted on the 3d April, 1837, from Robbin Island, where he had been on

detachment for twenty-eight days, living in a tent, and had good bedding, with diet of fresh meat, bread, salt, coffee, and sugar, but no wine, spirits, or vegetables. The days were warm at the time, but the nights were cold. His character is that of an habitual drunkard, and he had previously been often a prisoner in the cells, and frequently in hospital, in consequence of diseases brought on by constant drunkenness, such as diarrhœa, dyspepsia, &c.

His symptoms on admission at this time were pain in both legs, livid discoloration of the left knee, sponginess of the gums, fœtid breath, and extreme prostration of strength, with a rapid and feeble pulse. His breathing was free; urine turbid; bowels regular. He said he had been ill for six days before admission, and that at first he thought he had only got a severe cold; but being found unfit for duty, and his complaint increasing, he was sent to the hospital. He got an emetic in the first instance, and afterwards a brisk purgative of calomel, followed by an infusion of senna and salts, which produced several fœtid evacuations. His knee was frequently bathed with warm sea water, and he was ordered spoon-diet and vegetables.

On the 13th, two ounces of senna infusion, with two drachms of Epsom salts, were prescribed to be taken every morning fasting; also, one lemon daily.

On the 15th, the knee was found to be much swollen; tongue foul; gums and breath improved; bowels free.

Continue same treatment.

On the 17th, the application of warm sea water to the knee was discontinued, and warm vinegar and water substituted; and by the 20th a considerable amendment had taken place both in the local and constitutional symptoms, and his appetite was much improved. The purgative infusion was continued daily, and he was now ordered two gills of wine and low diet, as well as an additional supply of vegetables.

By the 24th the knee had resumed its natural size, and the integuments their natural colour. His gums had got perfectly well, and his appetite was good. His diet was now further increased, and he was marked convalescent.

Some cases of the same disease came under my observation, treated in the

* For the Reports alluded to, see our vols. for 1837-8.

98th hospital; and I had reason to believe that the same antiphlogistic plan there adopted had certainly a decided advantage over the tonic and stimulant treatment employed by some practitioners.

Note.—The first decided trial made of the antiphlogistic mode of practice in scurvy at the Cape, was in the 98th hospital; and the marked success which attended it convinced Mr. Armstrong, and others who had before witnessed the effects of a tonic and stimulant plan, or of a vacillating, partial, and mixed one, that the disease did not depend simply on general and local debility, but on a cachectic or depraved condition of the constitution, which required alteratives and correctives for its successful treatment — remedies of a very different nature from tonics and stimulants. The report of Assistant-Surgeon Armstrong, 98th regiment, has already been published.—J. M.

Report by Surgeon King, of the East India free-trading ship "Coromandel."

Cape Town, 1837.

On the 3d January, 1835, thirty invalid soldiers, and five others in health, of his Majesty's service, were received on board the East India trading ship "Coromandel," of 650 tons (Captain Boyes), at Calcutta for England. Two of the former died at an early period of the voyage, one from chronic dysentery, the other from obesity. The remaining 28 invalids were men who had served from twelve to twenty years in India, after being in the Peninsula. They were generally of irregular habits, much given to ardent spirits, and frequent inmates of the hospitals. Several of them had been in hospital for nearly four years immediately preceding their embarkation.

Their diseases were chiefly sequelæ of jungle fever, hepatitis (acute and chronic), dysentery, pneumonia, syphilis (one had a syphilitico-cancerous sore on the penis), and one was a case of mania. Their diet on board ship, as stipulated for by the government, besides biscuit, tea, cocoa, and sugar, consisted principally of salt-beef, 1 lb. 3 oz. three times, and 1 lb. salt-pork and pea-soup twice a week; once soup and bouilli (preserved), and once bread and cheese, with suet pudding. The soup and

bouilli was the only fresh animal food stipulated for. They had also one gill of vinegar each per week, and mustard, &c. for condiments.

The medical comforts consisted of 60 pints best lime juice, 17 dozen of sherry, and 8 dozen port wine; several dozens preserved gravy-soup, and about 160 pounds of sago: also warm clothing, as quilts, flannels, blankets, &c. to be served out to them when necessary.

On the 23d March, when the ship reached St. Helena, scurvy had not made its appearance on board. The troops were there supplied with cresses, cabbages, and other fresh vegetables in abundance; and the ship remained only twenty-four hours. A few days after leaving the island a case of scorbutus occurred, and the disease continued in a subdued state while in the warmer latitudes. The ship was becalmed seventeen days between the Line and the latitude of Sierra Leone, during which time several men became slightly affected. The heat there was excessive, being 85° Fab. in the cuddy. The atmosphere was close and muggy, and every one on board suffered from it, but particularly the invalids. Every attention was paid to keep the berth ventilated, and the men on deck in the open air. By the time we reached the higher trade latitudes, the disease was gaining strength daily, and began to commit desperate ravages amongst those who had suffered much from disease, and had been mercurialized in India; and before the ship arrived in England (on 23d May), all the troops but one were more or less affected with scurvy; and the seamen also shewed commencing symptoms of it; but none of the cabin passengers or officers of the ship became affected.

The earliest symptoms usually observed were:—The gums thickened, soft, and easily made to bleed; a small pulicose eruption on the lower extremities; and about the same time the muscles of the thigh or leg became stiff, hard, painful, and a little tumid; and after a day or two the skin became yellow over the pained part. The discoloration soon assumed a purple hue, and when in the situation of old sores, they opened afresh. The tongue was white and the breath fetid. The stools were generally pale; the urine scanty, with a whitish sediment. Occasionally there existed considerable lassitude, and the

countenance was sallow. As the disease went on, all these symptoms became aggravated; the gums bled even from the pressure of the lips, and the teeth became so loose as to be lifted out of the sockets by the finger and thumb. The discoloration of skin was now very dark, the lassitude excessive, and the patient unable for exertion. The pulse was often 140, and thready, and some hours before death imperceptible. The eruption and discoloration of the skin usually faded along with the sinking of the pulse. In some the appetite appeared to be good, in others bad; and they grumbled at fresh medical comforts. In this state I have known some of the men walk across their berth, get shaved, return to their hammocks, and be dead within fifteen minutes. They generally died suddenly. Diarrhœa generally set in twenty-four to forty-eight hours before death.

In many of the most severe cases the onset was not remarked, from the men skulking and keeping out of sight, through fear of having their allowance of grog stopped; but the first symptoms of the disease were, general lassitude and pain of the limbs, with tenderness of the gums.

Between the end of March and 27th May (when the the troops were landed at Gravesend) five deaths happened from the disease—one at sea, three after making the land, and one about fifteen minutes after he was put on shore, and after drinking half-a-pint of gin.

The treatment consisted of fresh diet, viz. preserved soup, rice, sago, mutton, &c. Lime juice was freely given, and sherry or port wine (6 to 12 oz. daily), with a table-spoonful of yeast several times a day. I have seen beneficial effects, though of short duration, from the use of vinegar; the apparent improvement was considerable, the pulse becoming stronger, and the anxious expression of the features going off. Several were allowed beer, or brown stout, but their only effect perhaps was that of sustaining life a few days longer, without mitigating the disease. Sixty pints of lime juice of the best quality were expended, and served out in proportion to the exigencies of the several cases.

In patients whose constitutions were shattered by previous disease or long residence in India, these means had the effect of staying the scourge, but did

not completely eradicate it from, or prevent its baneful influence on the system. In them the time required for an *imperfect* cure averaged about 23 days, and the disease generally recurred after they returned to the usual ship diet.

The men were allowed plenty of fresh water, their berth was often scrubbed, and kept as well ventilated as possible, and they were obliged to keep on deck during the day; and some of them, in fine weather, slept there during the night. Diarrhœa was curbed by opiates, taken by the mouth, or given in enemata; but its recurrence a second or third time usually hurried the term of existence.

One of the men who was severely affected with scurvy was upwards of 50 years of age, and, during the existence of the disease in his own person, he was seized with an epileptic fit for the first time in his life. He was bled, and afterwards given vinegar to drink (wine-glass fulls repeated many times a day, a remedy I have known to prevent and shorten hysterio-epileptic fits in females after bleeding has been premised), and he recovered.

Morbid appearances.—I have little to state in regard to the pathological condition of the organs. In one case, the external appearances were very trifling, only a few points of pulicose eruption on the legs, and the gums shewing a thin edge of sponginess; but the internal condition was far more serious than in any of the other cases. This man had lost vision from venereal ophthalmia, and had been affected for several years with "chronic cough." When this patient first made application to me (he skulked for several days, that his messmate might have his grog) he was unable to stand for a few minutes, and would have fainted if kept upright, and so rapid was the crisis that he died the third day, on being lowered from his hammock. On inspection, the right ventricle of the heart was found ruptured near the apex, and several ounces of blood and serum were effused into the pericardium. This ventricle was paler than usual in several places, and the left one was only of about half the usual thickness. The heart altogether was of an unusually small size. The right lung was much destroyed from tubercular abscesses, and the surface emphysematous, the air-cells being distended into considerable sized bladders.

A small portion of osseous substance was found in the substance of the lung near one of the abscesses, at its root. The appearances in the mucous membrane of the intestines I cannot speak of now with certainty, but several cases shewed ulceration in the colon, and other marks of irritation. The liver had also large cicatrices formed of a caseous appearance, and in one man the pelvis of one kidney was almost completely destroyed; these last, however, were marks of former disease.

REMARKS.—The quantity of salt provisions allowed is evidently too great; the men are unable to eat it at one meal, and usually keep part for supper the same day, and for breakfast next morning; a larger proportion of fresh provisions is necessary for invalids. It is necessary that invalid soldiers keep on deck during the day, and sleep on deck when the weather and their state of health will permit, as crowding below is very injurious to their health.

With respect to the cause of the disease in the case of the man who had the sore of the penis, and who was seized with scurvy, there could not exist a suspicion of salt provisions having given rise to it, as he did not eat salt provisions of any kind while on board, and I ascribe its origin in him to his confining himself to the berth, from whence I could only get him once on deck. Before the scurvy became general among his companions, his sores looked remarkably healthy, the swelling and irritation of the surrounding parts were greatly diminished as well as the pain, and he said he felt much better in every way than he had done for many months before he embarked. The cause therefore seemed to be an *impure atmosphere*, arising from the foetid breath and effluvia of many scorbutic men, and which could not be obviated in consequence of the inclemency of the weather, which was wet and cold. He died with all the symptoms of active scurvy; but I cannot pretend to say if the exhalations from the breath, &c. of a scorbutic patient be capable of producing the disease *specifically*, after the manner of an infectious complaint.

The only man among the soldiers who escaped the disease at this time was a maniac, who called himself the King of Hanover, and he never got the slightest symptom of it. This man was

almost constantly on deck, and always slept on deck under the spars. He only went below *sometimes* to eat his victuals. He took much exercise, kept walking about greater part of the day, and never had a dose of medicine the whole voyage.

In 1835-36, when on a second voyage to India, on the outward bound passage one of the men belonging to the ship's band of musicians became affected with scurvy. He suffered from it for the first time in 1828-29, for several months on board an East India-man, and in every voyage he afterwards made, he suffered from the disease soon after passing the Cape. In January, 1836, about forty-two days after leaving Table Bay, (where the ship remained six days), it made its appearance in him, in the rectus femoris muscle, which felt hard and stiff, and the skin immediately over the part became yellow: the yellowness extended up the thigh, and round towards the hip; most of the other usual symptoms were present also, but his appetite was good, and he did not feel languid. The treatment principally consisted in a diet of rice or sago, occasionally mutton soup with a small portion of fresh mutton, a quart of cider daily in divided doses and at intervals of four hours, with a table spoonful of yeast to each dose. The discoloured part was fomented with warm salt water, and a stimulating embrocation applied. In seventeen days all appearances of scurvy had disappeared.

When the symptoms first came on, we had been out forty-two days from Table Bay, and had experienced a hurricane, and eight days of very close muggy unhealthy weather. On two previous occasions that he was attacked under my care, the same treatment above described was adopted, with the exception of lime juice having been used instead of cider; and recovery at each respective attack was not complete before the 23d and 30th day. On the homeward passage to England in 1836, the scurvy again made its appearance in him, and also in one of the other seamen, three months after leaving Calcutta, on the 12th July, in lat. South, 30° 9', East long. 13° 59'; we had one month of almost perfect calm in the Bay of Bengal, and from the time we passed Ceylon, heavy gales in succession, until we reached the Cape, about the 17th July. There was much rain and sea

water shipped, and the men were often wet for many hours together, and their bedding also frequently drenched. In this attack the teeth of the man of the band before-mentioned became loose; his gums were very spongy, and bled from the motion of the lips; the pulicose eruption came out on the legs, and discoloration of the skin appeared, with hardness and stiffness of the muscles. The seaman had lumbago in addition to the scorbutic symptoms. The diet in the one case was as above stated, in the other it was not materially altered from the usual diet of the ship's company; and as medicine they had a mixture made of gr. x. Potass. Oxymur. ʒiiss. to ʒij. acid. muriat. to a pint of water. The acid was first diluted with an equal portion of distilled water, and poured on the chloride of potass in a bottle, letting it remain until the disengagement of gas had nearly ceased. A pint of water was then added, and of this mixture they each took a small wine-glassful (ʒiiss. to ʒij.) every four hours. When properly made, the water ought to absorb the whole of the gas, (*one* part of water absorbs *three* of chlorine gas) and I consider the gas to be specifically necessary*. They were also ordered to gargle their mouths with this mixture, and the gums ceased to bleed after one or two applications; and the perfect cure of the disease was also uncommonly rapid, for no appearance of it remained after the eighth day from the time they began to take the mixture, and these men did not require to apply again during the passage. The only additional medicine prescribed was a purgative of calomel and compound ext. of colocynth.

Several other seamen who shewed incipient symptoms of the disease before the end of the voyage, took of this mixture with like beneficial results. We arrived at St. Helena on the 23d June, and England on the 5th of September.

From the unprecedentedly quick recovery of these two men, and the preven-

tive and curative effects of this remedy on others, I shall be anxious to try it again if occasion offers, and one object will be to ascertain whether scurvy is curable by it during the continuance of men on the ordinary ship's rations.

The two men above mentioned, before they left the ship, requested to have the prescription, declaring that they never experienced such speedy relief from any other medicine.

[To be continued.]

MEDICAL SCHOOL OF BONN.

To the Editor of the Medical Gazette.

SIR,

A SHORT account of the medical school of Bonn, the newest and one of the most flourishing of the German universities, may not be without interest to some of your readers.

Bonn is situated on the Rhine, about 18 miles above Cöln, in a pleasant country, and one of great interest to the geologist. The university buildings here are spacious, and none of the lectures are delivered in the private houses of the professors, as in some other universities. Besides lecture rooms, &c. they contain the medical, surgical, and obstetrical clinics. The medical clinique consists of two wards, one room, very large and handsome, for females, containing about twelve, and one for men, with about eight beds. It is under the superintendence of Dr. Nassé, who has acquired considerable reputation in cases of insanity, is a man of extensive knowledge, and intimately acquainted with English medical literature. When a patient is admitted, the case is immediately handed over to one of the students, who undertakes its treatment. He has to make out in Latin the history of the case, detail the symptoms, give a diagnosis and a prognosis, and propose a method of treatment. All this he does with a minuteness of detail quite unknown in England, and reads it aloud to the physician for his criticism, and continues to write a daily report, so long as the case is in the house. This has undoubtedly the effect of making the pupil examine the case very minutely, and obliges him to read books on the disease in question. The treatment is, however, mainly that of the physician, whose

* I find that the chlorine gas is not disengaged from the potass if much (indeed if any) water be added to the muriatic acid, when it is poured upon the oxymuriate of potas.; and if the efficacy of the mixture depends upon the quantity of gas absorbed by the water, I think it would be better to pass the gas through the water by means of a curved tube, as it becomes evolved. The mixture, as here proposed, is rather too strong for use, (at least with ij. dr. of acid), and would be improved by an additional quantity of water, and some honey, sugar, or liquorice.

"suadeo" is always expected to be followed. The minuteness in detailing symptoms which is thus encouraged, and the length of time devoted to a particular case, can, it must be confessed, be of much advantage only to the beginner, and is apt to degenerate into what would be called trifling in England. But I believe that this may be considered as a fair average account of a German clinique. Attached to the clinique, is, what is termed the polyclinique—an admirable arrangement, which enables the students to visit in the town those cases which are not admitted into the hospital.

There is one doctrine very prevalent in Germany, namely, that which attributes a great many diseases to suppressed secretions, especially of the perspiration of the feet. Patients are invariably questioned on this subject. I remember the case of an old man labouring under violent, apparently functional disease of the stomach. Some one discovered that he had formerly been subject to feetsweats, which had latterly ceased, and accordingly his feet were subjected to stimulant frictions, in hopes of restoring the secretion, and thus, as a matter of course curing the disease.

In cases of fever, saline treatment, with the use of acids, seems to be the common one, and mercury to be little in use. I saw a case of malignant scarlatina in an advanced state. Any remedies would probably have been ineffectual: but nothing was ordered but an acid draught, and sponging the body. The physician recommended those of the pupils who saw this case, to take a small quantity of belladonna every day for some time, as a precautionary measure against infection, though he did not profess to have implicit confidence in the success of the measure.

One case of intermittent fever, where the fever was nearly subdued under the use of arsenic, but a permanent enlargement of the spleen remained, was much benefited by a free incision being made in the region of that organ, which was kept open for some weeks by a stimulant ointment.

The surgical clinique of Dr. Wutzer is said to be very well conducted. A recent operation in a case of opacity of the cornea, where a portion of the cornea from the eye of a sheep was inserted in the place of the opaque one removed,

was followed by violent inflammation, and failed. I am sorry that I was unable to obtain any very accurate details of the case.

Not least well managed is the obstetrical clinique of Dr. Killian, the author of a very good book on Midwifery. But of this I had not occasion to see any thing.

At the distance of 6 miles from Bonn, is the very extensive and well-conducted Lunatic Asylum of Liegburg, situated on a commanding height. There are about 200 patients, who are arranged in three classes, according to the violence of the case. Here, as elsewhere, the doctrine of suppressed secretions was prevalent, and I was told that next to mental these were the most frequent causes of madness.

Among the lecturers on the different branches of medicine, who are very numerous, perhaps one of the first is Dr. Naumann. It is usually the custom in Germany, to appoint a person professor only in a particular faculty, and not to tie him down to a particular subject. The general effect of this is probably good, as it enables him in most cases to choose for his lectures the subject most congenial to his taste. I may here remark that I believe there is a very general want in Germany of something corresponding to our English hospital practice: the cliniques, *i. e.* clinical ward in all the universities, not excepting Berlin, being small and crowded with pupils, though often admirably conducted, affording no equal advantage; the consequence is, that young physicians feeling this, when they have time and money, resort to the larger hospitals of Vienna, and some times to the clinique of Professor Krukenberg, at Halle, which last is looked on as the first in Germany. And this leads me to remark, what is I believe not generally known in England, that the degree of M.D. commonly easily acquired, does not entitle you, at all events in Prussia, to practise, until you have been examined by a superior board appointed for the purpose.

Bonn is well provided with lecturers on Natural History. The Zoological lectures of professor Goldfuss (whose work on the Petrifactenkunde is so well known) are very good: Travinarius the botanist, Noeggerath the mineralogist, and some others, have also obtained some name in their respective sciences.

The museums in a university of so recent an origin are necessarily not very complete. Yet the collection of zoology is very good, and that of minerals and rocks illustrates well the structure of the volcanic district in the neighbourhood. The anatomical museum is a spacious building, recently erected, and contains a well arranged collection of specimens chiefly of morbid anatomy, which is daily increasing. The beautiful botanical garden laid out according to the natural system, must not be forgotten.

The students of Bonn, about 700 in number, rank on the same scale as those of Göttingen, and, as a mass, are probably more gentlemanly than in most German universities. They appear to read but little, and the great object in the lecture-room is to take as full notes as possible of the words of the professor.

Bonn offers many advantages to those who wish to study the German language, and at the same time see something of German medical practice. It is not so cheap, and German is not spoken with such purity as at Göttingen; but it is more accessible, and a pleasanter place of residence.—I am, sir,

Your obedient servant,
J. M.

Berlin, Nov. 8, 1833.

UNION OF TWINS.

To the Editor of the Medical Gazette.

SIR,

IF you think the following case worthy a place in your valuable journal, as it may be interesting to some of your readers, you will perhaps insert it.

Yours, &c.

WM. EAGLES JOHNSON,
Student of Guy's Hospital.

Borough,
Nov. 21, 1838.

On Thursday, the 15th instant, I was called to attend a woman in miscarriage. I was not there many minutes before I felt the heads of two children forcing their way down the vagina; in a short time they were born. I found, on examination, that they were male and female, joined to each other (the left side of the female to the right side of the male,) from about the third rib above to about the anterior superior spinous process of the os ilium below. They appeared to be between the fourth and

fifth month of uterine gestation, perfectly formed in all their parts. One placenta supplied both children with nourishment, having one cord, common to both, attached to the lower extremity of the bond of union.

The woman accounted for this remarkable production, from the fact of having seen a similar phenomenon some time previously, and more recently a lithographed representation of the same.

EXTENSIVE DESQUAMATION.

To the Editor of the Medical Gazette.

SIR,

THE morbid preparation of the cuticular glove, which is illustrative of the case I now present to the readers of the MEDICAL GAZETTE, was in the possession of my father, Dr. Hutchinson. Whilst in the country last summer I obtained the following account of the case, together with a specimen of the whole and entire cuticle of the hand which came from the patient; and I now present it to the public, hoping that it may not prove uninteresting either in a medical or physiological view.

Mr. William Wright, of Saham Tong, in the county of Norfolk, attorney-at-law, about 50 years of age, rather of a weak and lax constitution from his youth, was seized with the following singular kind of fever. The medical gentlemen he at different times consulted were at a loss to know what name or character to distinguish it by. It has returned many times since, sometimes twice in a year, attended with the same symptoms and circumstances; but not to so great a degree since the year 1764 as before. It has been generally observed to come on after obstructed perspiration. Besides the common febrile symptoms upon the invasion of this disease, his skin itched universally, and more especially at the joints; and the itching was succeeded by a number of little red spots, with a slight degree of swelling. Soon after this his fingers became very stiff, hard, and painful at their ends, and at the roots of his nails. In twenty-four hours, or thereabouts, the cuticle began to separate from the cutis, and in ten or twelve days this separation was general from head to foot, when he has many times turned the cuticle off from the wrists to the fingers'

ends completely, like gloves; and in the same manner also to the ends of the toes; after which his nails shoot gradually from their roots, at first attended with exquisite pain, which abates as the separation of the cuticle advances, and the nails are generally thrown off by new ones in about six months. The cuticle rose in the palms of his hands and the soles of his feet like blisters, but contained no fluid under them; and when it came off, left the subjacent skin very sensible for a few days.

Sometimes upon catching cold before he has been quite free from feverish symptoms, he has had a second separation of the cuticle, but then so thin as to appear only like scurf; thus demonstrating the quick renewal of this part.

This gentleman was attended by Mr. Swallow, an eminent surgeon at Wotton, who has now one of those gloves in his possession.—I am, sir,

Your obedient servant,

THEODOSIUS CAYLEY HUTCHINSON.

October 17, 1838.

[We delayed inserting this with the intention of giving an engraving of the "glove." The artist, however, has found it impossible to give any satisfactory representation of it.—ED. GAZ.]

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abrégé."—D'ALEMBERT.

Urinary Diseases and their Treatment.

By ROBERT WILLIS, M.D. Licentiate of the Royal College of Physicians, Physician to the Royal Infirmary for Children, &c. &c.

WE have perused this work with the gratification which attends the consciousness of acquiring information; and have only been prevented by press of other matter from bringing it sooner under the notice of our readers.

Between the medical history of urinary diseases, by Dr. Prout, and their surgical history, by Sir Benjamin Brodie, we scarcely thought that there was room for a work of so much interest as the one before us. Dr. Willis has contrived to give a very comprehensive view of the functional derangements of

the urinary organs, and an account of the most formidable and important consequences to which they give rise—namely, calculus.

The work opens with a very interesting introduction on the physiology of the kidney, in which its instrumentality in purging the system of nitrogen is fully set forth. The food of animals, it is remarked, passes through the action of the lungs and kidneys into carbonic acid and urea, and the very interesting experiments of M. Chepat are adduced in illustration. According to his observations, each ounce of farinaceous food regularly afforded 9.9 grains of solid urinous excrement, each ounce of albuminous food 13.6 grains, and each ounce of albuminous food 17.3 grains, from which it appears that the quantity of azote in our food is a chief element in determining the amount of solid excrement in the urine; not less than ten-elevenths of all the azote introduced as food being thrown off by the kidneys.

It is now a well-known fact, for which we were in the first instance indebted to MM. Prevost and Dumas, that urea exists in the blood, and it is conjectured, from the composition of the deposits which take place in the joints of gouty persons, that uric acid may likewise do so. But Dr. Willis is anxious to guard against carrying the idea too far, of glands acting simply as mere organs of separation. The effect of injuries of the brain and spinal cord on the urinary secretion, shews clearly the agency of the nervous system in enabling the kidneys to eliminate their peculiar products. The average density of the urine has been variously estimated. Prout makes it 1.010 to 1.015; Willis thinks 1.015 a fair average, or, including children, 1.012. The greatest density the latter ever saw was 1.033. A succinct and clear digest follows, of all that is known regarding the chemical composition of the urine; to which, of course, we can do no more than refer.

Proceeding to the diseases, we find them divided into—1, Those which consist of functional derangements of the kidneys, and their immediate consequences; and 2, Those which depend upon functional derangements of the organs which excrete the urine.

In the first of these divisions we find several chapters devoted to various diseased conditions, and these we shall briefly notice *seriatim*.

Chap. I. relates to morbid states in which the secreting faculty of the kidneys is exalted, and the menstruum and readily soluble principles of healthy urine occur in altered absolute or relative proportions.

The first section of this chapter describes, under the name of Hydruria, those cases in which the discharge of urine is characterized by a deficiency of solid matter.

Considering the kidneys as one of the means by which superabundant fluids are discharged, we find their secretion generally increased in proportion to the quantity taken into the system. Here the kidney is acted upon by the supplies from without; but in other cases the kidney takes the lead, and the system follows, demanding supplies to furnish these glands with materials to act upon. Some interesting details are here given by Dr. Willis, which we subjoin:—

“ Sometimes, however, we meet with instances of diuresis in which an increased disposition to secrete on the part of the kidney has the lead, as it were, in the phenomenon—in which the kidney is not at work to drain the system, but the system is at work to supply the kidney. This state of things was observed and remarked upon very long ago, and it is to be found described in books under several names, such as *Diuresis*, *Diabetes insipidus*, *Polyuresis*, and *Polydipsia*, from the thirst that attends it, &c. Among the many remarkable histories of this malady which I have met with in the course of my reading, is that of a small artizan, aged fifty-five, who came into the Hôtel-Dieu of Paris to be treated for a bruise of his knee, from which he speedily recovered. The uncommon thirst of this man, and the incessant calls he had to make water, attracted attention, and it was found that from the age of five years he had had a constant thirst upon him, and been affected with a diuresis commensurate with his thirst. From the age of sixteen he had not drunk less on an average than two bucketfuls of water daily. During the ten days he remained in the Hôtel-Dieu, he consumed on an average thirty-three pounds of water every day, often swallowing two litres (above two quarts) at a draught; his solid food was about one pound and three-quarters, and he seems also to have had a little wine. His evacuations

urine, and, at the most, one pound of fæces. Yet this man looked and seemed well; he possessed the ordinary strength of a little man of fifty-five; he was the father of several children, and suffered no inconvenience save from the necessity of drinking, and voiding his urine so frequently. The urine scarcely exceeded pure water in specific gravity. Reduced by evaporation and having yeast added, it gave no sign of fermentation. The urine was certainly quite healthy, only very much diluted. Several interesting cases of the same kind were collected by Dr. S. F. Simmons. A woman, aged 40, and the mother of many children, had suffered from continual thirst and the discharge of a profusion of fetid urine since the time she was a child. Compelled to quit her father's house on account of the quarrelling to which her large consumption of water gave rise, she came to Paris and entered into service. Here the increased quantity of water that was used in the family attracted attention, and it was found that the servant girl was in the habit of drinking two or three pailfuls of the pure element every day. A shoemaker having paid his addresses to her, she contrived to conceal her infirmity from him till after the marriage, when of course he discovered the real worth of his bargain, and found that all his earnings were not sufficient, in the depth of winter, to buy his wife water, so that he had to collect and melt snow and ice from the house-tops for her use. This woman enjoyed very good general health. Dr. Desgranges has given several cases of the same kind. One man at the age of thirty-two had been affected with diuresis and thirst from the age of four years, and had at one time been in the habit of drinking eighteen bottles of water daily. Another young man, until he had a pleurisy at the age of eighteen or nineteen, had been the subject of a similar infirmity; but a blister applied to the chest for the inflammation having continued to suppurate for the space of twenty-five days, he had found himself cured of his extraordinary thirst and diuresis. The same writer quotes a case from an American journal, in which a young man aged twenty, stout, active, and in the enjoyment of good health, was in the habit of consuming six gallons, or forty-eight pints, of water, and passing a

commensurate quantity of urine every day."

In hysteria the occurrence of large quantities of urine is known to all. Dr. Willis thinks the secretion is but little altered, as to the quantity or relative proportion of its ingredients, though the watery menstruum is very much increased. He has thought the chloride of sodium, perhaps, more abundant than in perfectly healthy urine. The diuresis which the more advanced in life sometimes labour under, seems to be essentially the same in character.

In the treatment of this form of disease, or hydruresis, the diet must be particularly attended to, especially as regards restricting the quantity of fluid as much as possible. While the demand upon the kidney is thus diminished, the action of the skin must be augmented as much as possible by warm baths and the diligent use of the flesh-brush; the bowels to be regulated by mild purgatives, avoiding mercury. Hyoscyamus and opium are also of use, as are tonics, particularly the bitters, and iron.

This brings us to the anazoturia, wherein we have a deficiency of urea; not a merely relative, but an absolute deficiency. Under this head, in Dr. Willis's opinion, come almost all the cases which have been cured under the name of diabetes. The usual characters are as follow:—

The urine is abundant, limpid, straw-coloured or colourless, and with a very slight faint smell. At first it is neutral or slightly acid, but soon becomes ammoniacal, with a "fine creamy" pellicle, consisting of the ammoniaco-magnesian phosphate. According to our author, this form of disease is not unfrequent among the children of the poor.

"I have at this moment," says he, "three children under my care at the Royal Infirmary for Children, affected with urinary diseases, two of whom present the form of malady to which I have ventured to apply the title of *anazoturia*. The one of these children is a boy three years and a half old, and has been weakly from his birth. His extremities are emaciated, but he has a large, soft, protuberant belly. He is spiritless, and disinclined to move and play about. His appetite is voracious, and his thirst incessant. The poor little fellow will drink nearly a pint of water at a time if allowed, and is not satisfied

with less than about four pints in the course of the day and night. He makes water in considerably greater quantity; which was to have been expected; for he has a constant craving for food, and cries until he is indulged with every thing he sees—meat, bread, potatoes, cabbage, and raw lettuce. The bowels are constipated, and the feces present pieces of undigested aliment, particularly potatoe, carrot, &c. The urine first brought to me by the mother was so free from every one of the sensible properties of urine, that I insisted it must be the rinsings of the bottle, returned into it by mistake; but I soon satisfied myself that I had the veritable urine of the child, by getting him to make water before me. This urine did not differ in appearance from common water; it was quite limpid, absolutely colourless, all but free from odour, and neutral when passed. It became in the slightest degree opalescent or milky after standing ten or twelve hours. In specific gravity it corresponded as nearly as possible with distilled water; at first I even thought it lighter, but this was from trying it with a new hydrometer, the scale of which I immediately discovered to be set about a degree too low. Brought to the boiling point it let fall no precipitate, a few bubbles of air (probably carbonic acid gas) being disengaged. No effect followed the addition of a solution of oxalic acid. Caustic potash caused the subsidence of a few flocculi; 1000 grains evaporated slowly left but a fraction of a grain of residue, which appeared to consist entirely of mucus, lithate of ammonia, and the phosphatic salts; but it must also have contained a small quantity of urea and colouring matter; for the urine kept two days in a temperature of about 65° Fahrenheit, became very faintly ammoniacal. The quantity of residue I had to deal with was too small to enable me to speak with greater detail."

Numerous cases which have been recorded in various publications, are referred by Dr. Willis to this head; among others, he particularly alludes to the papers of Mr. Macgregor and Mr. Snowden, in this journal, and also to the valuable observations of Dr. Graves. The disease is indicative of deeply-seated constitutional disturbance, and must always be viewed with apprehen-

sion; and even of those apparently cured, the amendment is occasionally but temporary. The great objects to be had in view in conducting the treatment, are to restore the functions of the stomach, bowels, and skin, and to diminish the excitement of the kidneys. The medicines by which this is to be attempted are chiefly mild aperients, tonics, diaphoretics, mild anodynes. Toast-water, slightly acidulated with muriatic or nitric acid, is recommended; to be taken, however, in quantity not greater than is indispensable for the alleviation of the thirst, which is always urgent in such cases.

The azoturia, wherein we have a superabundance of urea, comes next. High living and a free action of the skin will at any time increase the proportion of saline ingredients in the urine; but in some cases this, as regards the proportion of urea, is habitual, and forms one of the modifications of urinary disease described as diabetes. The specific gravity of such urine is generally high (between 1.018 and 1.035), but not invariably so; Mr. Rees having, in the 19th volume of this journal, detailed a case in which it was so low as 1.008. In this form of the disease, the calls to void the urine are not only very frequent but extremely urgent, owing to the great irritability of the bladder. The disease is chiefly met with among those who have formerly lived freely, and have been originally of nervous temperament. There is thirst, gnawing at the pit of the stomach, and a peculiar hollow-eyed anxiety of expression. Children are frequently subject to this form of the disease; a circumstance to which Dr. Venables some years ago directed attention. This form of disease has been observed to alternate with, and to be the precursor of, the worst forms of diabetes, with saccharine urine. Still the disease is to be regarded, if taken in time, as frequently amenable to remedial means; the function of the kidney being as yet "not so much altered, and simply increased." General as well as local bleeding are frequently requisite; cupping on the loins, and blisters, followed by tonics and chalybeates, opiates, and regulated diet.

This chapter concludes with some short directions relating to the modes of examining the urine, and with them we shall also terminate our present notice,

meaning to resume the subject in an early number.

"The physical and chemical investigation of the varieties of morbid union comprised in this chapter, is to be undertaken on the same principles. The general appearance, degree of transparency, disposition to deposit, odour, &c. are to be noted. The specific gravity is then to be ascertained, a piece of knowledge easily procured by means of an instrument,—hydrometer or urinometer, sold in the shops for the purpose. A given quantity of the urine, say 1000 grains, is then to be slowly evaporated, at a temperature not exceeding 160 or 200 degrees of Fahrenheit, till it ceases to lose weight. The quantity of extract being ascertained by weight, the proportion of the solid matter to the water will become exactly known. The extract is next to be digested with strong boiling alcohol (sp. gr. .833,) which will take up the urea and salts (the lactates) which are soluble in alcohol. What is dissolved is to be poured off; what remains is to be washed once or twice with a little fresh boiling alcohol, which is to be added to the first. The alcoholic solution is then to be reduced by slow evaporation to the consistence of extract, or till it ceases to lose weight, and its quantity ascertained. The saline mass which was insoluble in alcohol, is to be treated with distilled water at 60 degrees Fahrenheit, two or three times, and the different solutions being added together and evaporated to dryness, the quantity of saline ingredients,—the soluble chlorides, and alkaline phosphates and sulphates, will be discovered. The insoluble matters, consisting principally of the earthy phosphates which remain on the filter, being dried, are to be weighed. They are afterwards to be digested with caustic potash; and being dried and weighed again, the quantity of mucus or other animal matter will be estimated by the loss of weight, if any, which is sustained. This is as much as is required for medical purposes. For every information requisite in conducting a more minute analysis of the urine, I beg to refer to the excellent treatise of Mr. G. Rees, entitled, 'On the Analysis of the Blood and Urine in Health and Disease.' 8vo. London, 1836."

DR. CONRATH ON THE BATHS OF FRANZENSBAD.

Ueber die neuen Bade-Anstalten zu Franzensbad, und die hier erst erfundene verbesserte Methode, kohlensaure Eisenwässer auf Flaschen zu füllen und zu versenden. Von M. D. CONRATH, Brunnentarzte. (Zum Vortheile des Franzensbader Armenhauses.)

On the new Bathing Establishments at Franzensbad, and the new and improved Method first discovered there of bottling and exporting carbonated Chalybeate Waters. By M. D. CONRATH, Physician at that Watering-place. For the benefit of the Franzensbad Poor-house. 8vo. pp. 90.

FRANZENSBAD is situated near Eger, in Bohemia, and is celebrated for its mineral springs, which are used both for bathing and drinking. There are four springs, all of which are nearly of the same temperature, or about 53° of Fahrenheit; they contain a quantity of solid matter varying from 26 to 33 grains in the pound, consisting chiefly of sulphate of soda, carbonate of soda, muriate of soda, and carbonate of lime, with a little carbonate of iron, besides a considerable quantity of free carbonic acid gas. According to Dr. Conrath, these baths are indicated in general debility after violent uterine hæmorrhage; weakness and impotence from sexual excesses; the debility following feverish and chronic diseases, or the too protracted use of mercury; diseases of the uterine system proceeding from simple debility; general cachexia and dyscrasia, shewing itself in the form of atonic gout, chronic rheumatism, obstinate ulcers, scrofula, and rickets; in dyspepsia, disordered secretion of bile, migrain, hemorrhoids, and hypochondria, when they arise from mere weakness; chronic diseases of the nerves proceeding from debility; and lastly, as a preparatory course to stronger and more heating chalybeates, as well as an after course when resolvent and weakening waters have been previously used. He does not mention the temperature at which they are generally employed, but gives the case of a young lady who used them with great advantage, and could never bear the temperature higher than 86° of Fahrenheit, and at last took the baths at 77°. Dr. Granville says

the baths are seldom colder than 90°, and never warmer than 98°.—(The Spas of Germany, 2nd edit. p. 303.)

The baths are contraindicated, says Dr. Conrath, in all kinds of fever, in inflammatory habits, and when the patient is disposed to active hæmorrhage, or to apoplexy; in cough attended with hæmoptysis; in tubercular phthisis, internal suppuration of any organ, and induration or scirrhus of the viscera; the venereal disease in its various forms; and congestions in the chest or head. Children, pregnant women, and the aged, should not use these baths without medical advice.

We pass over the account of the mud-baths, and the gas-baths, both of them most powerful agents in the cure of disease, as the reader will find them fully described in Dr. Granville's work. He mentions the case of a little girl who had long been afflicted with malignant scrofulous ulcers in both legs, and in whom, after eight gas-baths, all the ulcers, except one, were healed, and that one was in a fair way of following the others.—(The Spas of Germany, 2nd edit. p. 306.)

Dr. Conrath gives an account of the method of bottling the Franzensbad water for exportation pursued by Mr. Hecht; from which it appears that it is the joint off-spring of a hint given by Berzelius when he visited the place in 1822, of a method described by our countryman, John Masterman, which is to be found in Dingler's Polytechnic Journal, and of Mr. Hecht's own unwearied labours. The upshot of it is, that the atmospheric air is excluded, during the corking of the bottles, a gasometer filled with carbonic acid gas being so cleverly connected with the machine, that the vacant space requisite for the reception of the cork is instantly filled with carbonic acid gas. By this means the water can be preserved without decomposition, while other chalybeate springs bottled after the old fashion deposit the greater part of their iron; so that, as our author pleasantly observes, iron-fearing patients and physicians need not hitherto have been so frightened at exported chalybeate waters.

On the whole, there is a strong body of evidence in favour of the healing powers of Franzensbad. At present it is certainly not a very fashionable

watering-place, but this to many will be a recommendation. The drooping and disheartened invalid, worn out with hardships or pleasure, may get well at Franzensbad, without the constant inspection of his friends from Piccadilly and Cheapside. Such, at least, is the case at this our present writing; perhaps some few years hence it may be requisite for the shy and retiring patient to take refuge at the healing waters of Greece or Portugal.

MEDICAL GAZETTE.

Saturday, November 24, 1838.

"Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tueri; potestas modo veniendi in
publicum sit, dicendi periculum non recuso."

CICERO.

TESTIMONIALS AND CERTIFICATES.

WE intend to offer a few observations on three kinds of certificates and testimonials commonly given by medical practitioners. The first are those which are bestowed upon the candidates for vacant offices at hospitals and dispensaries. Of these it may perhaps be said that they sometimes err a little on the side of good-nature; but, after all, this defect is not of much importance. It rarely, if ever, happens that the scale is turned at elections by written testimonials; though if the eminent practitioners who give them should also add the weight of their private influence, an inexperienced observer might attribute those happy effects to written documents which are really due to a few spoken words. "We must bring in Tims," said by the proper man at the proper season, will do more than a quire of pen-and-ink certificates. Their worthlessness is known and appreciated.

We once, however, heard of a voter whose favour was to be secured by written documents. Some years ago we

were looking over the list of governors of a dispensary (in expectation of a speedy vacancy), with the aid of a friend eminently skilled in medical elections, and possessing an almost faultless knowledge of the method of reaching each vote at that institution. We went through the catalogue name by name. "Do you know Dr. A.?" "Yes." "Well, then, besides his own vote, he will get you this man and this." "If you can secure Vafer, you are sure of Simplicius, his son-in-law." "In the Saffron Hill district, you will find Surgeon T.'s name act like a charm, and draw shoals of voters into your net." At last we came to a Mr. P. "Ay, this man," said our infallible friend, "goes by the testimonials!" One, and one alone, was faithful to the spell—the single slave of the lamp among the governors of the Sun Street Dispensary!

On the whole, therefore, we have little or nothing to say against this class of testimonials. The only regret they cause us is, that the host of candidates who obtain the warmest testimonials with the greatest facility, and generally with the most justice, form but too strong an argument in favour of our old position, that the profession is lamentably overstocked; nay more, that it is overpeopled with candidates for employment, who, if we may use such a phrase, are not only legally but medically qualified.

Every hospital, and we believe we may add every dispensary in London, besides its staff of medical officers, has an ample list of supernumeraries eager to occupy their places—to step into retired men's shoes! Of these not one in five can have his hopes fulfilled. Can any thing be more melancholy than to see the crowd of expectants, most of them admirably qualified to fill the posts which they can never obtain, linger on in fruitless attendance, while their hair grows grey, and their spirits

fail beneath the stroke of disappointment?

Perhaps some of them may be more fortunate, and may be blessed with the place of assistant surgeon or physician at the age of 40; so that by the time he is 50 he may hope to be considered a rising young man. Dr. Caspar has given various causes for the shortness of life in the medical profession, but we do not recollect that he has mentioned the hope deferred, which makes the heart sick.

Mr. Lawrence, indeed, acts the part of Job's comforter on this point, for he tells us, in his Hunterian Oration, that "it has been a trite, but, I believe, most unfounded complaint, that genius is neglected, and that men of talent and information are precluded from opportunities of exertion and display by favouritism, monopoly, or other obstacles. Within my own experience, the difficulty has always been to find talent for the place, not opportunity for the talent. This, indeed, is natural; genius being rare, while fit occasions for its exercise are of constant occurrence."

Now this is true or the reverse, according to the height at which we pitch our standard of talents and acquirements. Suppose, for instance, that when a vacancy occurs at a London hospital, we require the person who is to fill it, not only to possess a sound and practical knowledge of his profession, but to be perfectly skilled in all the subjects set forth in the manifesto of the new University which we have lately brought under the notice of our readers: why, we might search London through and not find a candidate, nor half a one. So that the difficulty would be, as Mr. Lawrence supposes, to find [ideal] talent for the [actual] place, not opportunity for the [ideal] talent: or, if we were to be somewhat less *exigant*, and frankly confess that we would put up with a

Hunter or a Baillie, we might still be disappointed; London, and even several of the surrounding counties, might be ransacked in vain.

But if we descend a dozen steps lower, and content ourselves with men perfectly qualified to discharge the duties of hospital physicians or surgeons with credit to themselves and advantage to the public, and also capable of adding their mite to the stock of professional information—the difficulty is no longer to find, but to choose. It is a hard thing to reject the hungry applicants, and tell them, with the stern air of a Malthusian, that the table is full, and they must seek places elsewhere; yet this must be done, and is done every day.

Hence the testimonials we have been considering bear witness by their abundance to the wants and miseries of the profession, and tell of superfluous talent and unrequited industry.

Certificates of the second kind are those which testify the attendance of pupils on lectures, and hospital or dispensary practice. If testimonials of the first kind were comparatively inert, these are positively bad; for scarcely one in ten can be termed accurate. If a pupil hears three lectures out of seventy, can he be said to have attended the course?—if ten, to have been diligent? if thirty, to have been exemplary? The faces of teacher and pupil are sometimes mutually unknown; and it is recorded that a pupil in a celebrated school once asked Professor Stamen which was the professor of *materia medica*, and being informed that it was the very person of whom he inquired, immediately begged to have his certificate of attendance!

As for hospital instruction, even that is not followed by the bulk of nominal students as it ought to be. Dr. Latham in one of his clinical lectures, observes, that the majority of pupils do not follow

up a single case from its beginning to its termination, throughout the whole of their hospital attendance. But in this respect we are happy to say there has of late been much improvement. Still medical education will not be what it ought until these tricks are corrected, and certificates more nearly represent facts. Perhaps we might add, that medicine will not be effectually taught till medical schools are more nearly assimilated to classical and mathematical ones. At school, or the university, Euclid is not taught by masters merely dilating on the merits and explaining the difficulties of the Alexandrian geometer, but by the pupil, with the figure before him, giving the demonstration from his memory, and, when more advanced, supplying the defects of the latter by his invention. In like manner, if anatomy were really taught, the pupil should take up the bone, or the dissected limb, and demonstrate the parts to his instructor. This is the way that Baillie seems to have been taught by Hunter; though it is said that the pupil was obliged to pursue a more laborious method, and demonstrate without having the preparation before him.

At a real school, we take it for granted that some method would be adopted, if not of compelling the attendance of students, at least of noting the absent, refusing certificates to the incorrigible truant, and reserving epithets of praise for genuine diligence.

Till this happy era arrives, the mock certificates must continue to be one of the sorest and weakest points in medical economy, and though familiar from usage to professional men, scarcely to be mentioned to the laity without a blush.

But if we object to these certificates as *positively* bad, what shall we say to those which are *superlatively* so—to the testimonials which it has been of late

the fashion to give to quacks and demi-quacks in all their varieties?

A madhouse, a solution of copaliba, two sorts of clyster-pipes, certain miraculous spectacles, and a universal ointment, are among the sundries which we have seen violently puffed off, with the appended testimony of medical men—aye, and distinguished medical men, too. It is strange, indeed, to see some of the first names in our profession tacked to quack advertisements, and not to hear that they are forged. In certain instances the letters written have been garbled, the pill- or spectacle-monger leaving out some of the most essential words, and thereby heightening the praise to any required amount. The men of salves and eye-glasses may have learned this art from book-makers, who practise it with great ingenuity. Thus let us suppose that a reviewer had said, “in spite of numerous errors, Mr. Bolus’s treatise on capsicum may be made *useful to students* in a future edition,” your sharp-eyed selector picks out the three words which we have put in *Italics*, and prints them as the reviewer’s opinion. But in the quackeries we have just before mentioned, the opportunity of garbling ought not to be afforded; no letter should be written to a professed quack, or if any accident made this absolutely necessary, it should not contain a word about his nostrums. A Frenchman once wrote a *Réponse au silence de M. Vaugelas*; but few quacks would have the ingenuity to make a puff out of nothing. As for the things themselves, the unwearied zeal with which they are advertised is enough to make any reasonable person doubt their virtues. “Do not cry roast beef,” says an old saw; to which we would add as a new commentary, “You need not.” Very little proclamation of its merits will suffice for a really good invention, while a thousand a year has sometimes been spent to keep up the

bad eminence of a nostrum. The quack medicine sinks into oblivion as soon as newspaper aid is withdrawn, while a useful discovery

“*Volitat vivu, per ora virum.*”

DEATH OF BROUSSAIS.

PROFESSOR BROUSSAIS died at one o'clock on Sunday morning, the 18th instant, at his country-seat of Vitry. He was born in St. Maloes in 1773. This celebrated reformer had acquired an immense celebrity, and his loss is certainly one of the greatest that medicine has suffered for some time. The author of the examination of medical doctrines—the founder of physiological medicine—the ardent defender of inflammation and leeches—has, by the power of his systematical genius, by the energy of his convictions, by the vivacity and even violence of his controversy, shaken medical theories to their foundation. During upwards of ten years he (the professor of the Military Hospital of Val de Grace) had to maintain the most animated discussions. He at first found no adversary to take up the gauntlet, but when he had founded a dissenting sect, preached the most redoubtable crusade against the doctrines of the school, and propagated the most violent schism, by which all the powers of the indefatigable *Athleta* could not prevail against the force of the faculty, the strenuous advocate exhausted all his strength in combating a re-action which he could not overcome.

Like all great reformers and founders of systems, M. Broussais has done good and evil. Impartial history will apportion the share of each; but from this day we may safely enrol the name of Broussais among the glories of France. —*Times, from French Paper.*

A subscription has been opened in Paris, for the purpose of erecting a monument to the deceased.

REPORT ON WEATHER AND DISEASE AT HAMBURGH, IN 1837.

JANUARY, February, and March, were very moist, but not cold; April was colder in proportion, bringing with it much snow

and stormy weather; May, too, was very rough. A high temperature first appeared with a clearer sky in the middle of June, and lasted till the 20th of August; after a violent thunder-storm on this day, a colder temperature prevailed until the middle of September, and was then succeeded by more sunny days, until the end of October. November and December were rather cloudy and foggy, than bearers of snow and cold. The thermometer attained its highest point in August, and its lowest in February.

The state of health in Hamburg in 1837 was far from satisfactory. The mortality, including 349 still-born children, was 5462, being an excess of nearly 1200 above the previous year, which is explained by the existence of four epidemics in the course of 1837. The number of births was 4904, including the still-born, being only 185 more than in the previous year.

The character of disease in 1837 was especially catarrho-rheumatic, and most decidedly so in the months of January, February, March, April, May, June, and December. In July it shared its dominion with the gastric form; August brought more gastric and gastro-rheumatic maladies; in September gastric disease particularly prevailed, which in October became mingled with catarrhal complaints; but in November the gastric character again predominated, which was most clearly shewn in the measles, which were common in this month, and bore a decidedly gastric stamp.

First epidemic: the Influenza.—The influenza appeared in the first days of January, and the cases became more frequent about the 5th or 6th; the epidemic reached its acmé between the 15th and 20th, and there were no fresh cases after the first week in February; so that the epidemic lasted five weeks. There was nothing in the preceding month that could be distinctly considered a precursor of the epidemic; it is true that the character of disease in December, 1836, was catarrho-rheumatic: but this is the regular form in our climate in December, when the weather is mild; nor did the phenomena of disease, either in quantity or quality, deviate from the ordinary catarrho-rheumatic forms. The attack of the influenza often came on, especially in robust subjects, with the rapidity of lightning; but in other cases there were precursory symptoms, as in catarrhal or rheumatic fevers, such as twitches of the limbs, shivering sense of confusion in the head, unquiet sleep, want of appetite, costiveness, &c. After these symptoms had lasted more or less time, there came on feverishness, which was generally exacerbated in the evenings, headache, giddiness, flow of

tears and heat in the eyes, with injected conjunctiva, cold in the head, cough, sore-throat, hoarseness, sense of anxiety and oppression about the chest, occasionally stitches in the side, pain in the limbs, and more especially about the lumbar vertebra, sleeplessness, loaded tongue, and disturbed digestion. But the most constant symptom of the influenza was the extreme sense of weariness with which it announced itself; and which, when compared to the same symptoms in other diseases, seemed to bear no just proportion to the duration of the malady, and the sufferings of the patient. Less frequently, the catarrhal phenomena were preceded by vomiting and diarrhœa: perspiration was not a common occurrence; but in some few cases where it was very profuse, it seemed to have a favourable influence on the course of the disease, as did also the epistaxis which was occasionally observed. A crisis seldom was ascertained by means of the urine, as the disease seemed more disposed to a resolution than to a crisis; yet some few crises seemed to take place by diarrhœa and herpes labialis. Bloody sputa were rarely seen, but the cough, which was violent and often spasmodic, sometimes produced early or profuse menstruation, and in pregnant women abortion, so that there were forty-one still-born children in the month of January. The discharge from the nose, as well as the expectoration, were similar in quality to those of catarrh in its different stages, but was often much greater in quantity; those, especially, who were suffering from chronic diseases of the chest, when they were attacked with influenza, expectorated enormous quantities. The cold in the head was preceded in some by a sense of burning in the orbit and its neighbourhood; in others, for the most part elderly persons, the pains in the calves and soles of the feet were uncommonly sharp. Some single cases were observed of salivation, swelling of the submaxillary glands, aphthæ in the mouth, *diarrhœa cruenta* in children, and strangury.

The duration of the malady was very various. Persons of robust constitution were often able to follow their business in two or three days, although the feeling of weariness had seldom disappeared so soon; children, on the whole, got well the quickest; while weak and sensitive persons had often to struggle with the disease three weeks and more. The average duration was from eight to ten days.

The extent to which the disease spread was unusually great; Dr. Rothenburg, indeed, supposes one-half of the population, or 65,000 persons, to have been attacked. The number of patients in the general hospital increased, from the 7th to the 14th

of January, from 1419 to 1502; and on the 21st reached 1558; from which number it gradually decreased to 1421 on the 1st of July. Of 900 active men in garrison, (officers and invalids not being included), 205 were attacked. Domestic animals, too, fell sick; in particular, dogs and cats were heard to cough. The influenza predominated so much over other diseases, that of 222 new cases of disease, which the reporter had to treat in January, 171, or nearly $\frac{3}{4}$, were pure cases of influenza, and the majority of the remaining $\frac{1}{4}$ were mere or less influenced by the epidemic. Contrary to the wont of other epidemics, but from obvious causes, the lower orders were, generally speaking, attacked later than the classes above them; in other respects, neither age, sex, nor rank, seemed to make any essential difference in the disposition to the disease.

With respect to complications of the disease, we must first mention affections of the chest. Elderly persons labouring under chronic bronchitis, often died at this time with the symptoms of suffocative catarrh, or paralysis of the lungs. Children with a badly formed thorax, &c. frequently sank under inflammation of the lungs. Pleurisy and pneumonia, however, also occurred in the prime of life, and in robust constitutions; especially when injurious exciting causes, such as getting wet through, had preceded; and then, on dissection, exudation or hepatization was generally found. It is scarcely necessary to mention to a practical man that the influenza frequently produced the germ of phthisis, and that the phthisical at that time endured additional sufferings. One very unfavourable complication was with affections of the brain, which were observed during the period of dentition, or as a metastasis from rheumatism. Erysipelas sometimes occurred. Of fifteen or eighteen patients attacked by this disease in the work- and poorhouse, eight died with symptoms of phrenitis. Gastric and polycolic attacks also occurred.

Inquiries into the contagiousness of the influenza would be as difficult as they would be here out of place; yet we will mention the observation made in the military ward, that when other patients were placed among those suffering under influenza, the former began to cough as soon as they entered the ward. As to the treatment, we cannot entirely agree with Dr. Behre, when he calls upon the physician to employ energetic measures from the commencement of the malady. We have not so often met with thoracic inflammation as an attendant on the disease as Dr. Behre, who designates the disease as an epidemic inflammatory catarrhal fever. When this complication did occur,

we were obliged to employ the lancet; but on the one hand, great caution was required in the repetition of bleeding, for fear of bringing on a collapse; and on the other, in the great majority of cases, if the diet was properly regulated, above all, if a suitable beverage was selected, such as gruel, Seltzer water, with boiling milk, and the like), the cure was very conveniently left to nature. It requires, of course, no special mention, that in many cases expectorants, demulcents, resolvents, &c. were useful remedies, which each practitioner selected according to his predilections or former experience. Apperients were advantageous in many cases, whether constipation was present or not. We cannot agree with Dr. Behre in thinking constipation a constant symptom in influenza, but we are of his opinion that emetics were generally of no use; for we will confess, that in the beginning of the epidemic, and particularly where nausea and gastro-polyebolic phenomena appeared to give a double indication, we tried to cut the disease short by an emetic, but never succeeded. As to the after-diseases, they have been already partly pointed out in the enumeration of the complications. It is obvious that long-continued blennorrhœa, chronic rheumatism, phthisis, œdema of the feet, general dropsy, and a protracted state of debility, must often have followed the influenza; but we must not omit to mention the observation of several physicians, that intermittent neuralgia made its appearance in several forms.

We may add historically, that the epidemic of 1837 bore a great resemblance to the one of 1557 (*Marcellus Donatus de Hlistor. Med.* p. 636; *Schweich die Influenza*, p. 59); to the one of 1658, described by Thomas Willis (*Willis Opp. Omnia*, Genev. sect. ii. p. 296); and to the one observed by Sydenham in 1675 (sect. v. cap. v.), where this experienced physician reminds us so impressively always to consider the *genius epidemicus* as the pole-star of the treatment, which genius in this epidemic could not bear the *ingens remedium molimen*, and repeated blood-lettings. Moreover the epidemic was very similar which lasted from 1731 to 1735, and which was described by Van Swieten (*Rautiln des Maladies Occasionées*, p. 283; *Schweich*, l. c. p. 81); the one of 1767 scarcely differed, but by having been less extensively diffused (*Schweich*, l. c. p. 102; *Gluge die Influenza*, p. 88). There is a still greater resemblance in the one of 1781-2, which was well described by Dr. Mumsen, a physician of Hamburg, in a pamphlet printed at Hamburg in 1782. Sleeplessness does not appear to have been so common in that as in our epidemic; and attacking the disease with powerful reme-

dies is bitterly censured, as being dangerous, and even fatal.

Second epidemic: the Mumps.—This disease appeared from May onwards sporadically; it began to be epidemic in September, and in October already began to decrease considerably; yet some cases were seen till the end of the year. It was extensively but not excessively diffused. The great majority of cases were children, from five to thirteen years old; the mumps were of an uncommonly favourable kind, hardly ever had a metastasis, and rarely required medical assistance. As far as we learned, they were fatal only in one case, where they were complicated with a chronic disease of the brain. They offered nothing worth mentioning, except that the submaxillary gland seemed to be attacked more frequently than usual.

Third epidemic: the Cholera.—We can no longer give the cholera the special name of Asiatic, as the experience of several years has taught us (unfortunately almost the only result that has been obtained) that there is no constant differential mark between the cholera observed of late years and the form which existed previously, and that the milder kind often passes into the more violent one.

In August, several kinds of bilious vomiting and diarrhœa occurred, sometimes accompanied by cramps in the calves—symptoms which about the end of the month took an unfavourable turn, so that in the bills of mortality there were four deaths from cholera, four from *cholera infantum*, and one from diarrhœa: but the first decided appearance of the more destructive kind was in September, in which month there were 102 deaths from cholera; in October there were 93 fatal cases, and in November 10, besides one of diarrhœa; in December there was not one. The whole number of cases must have been about 300, as almost two-thirds of those who were attacked died.

As this disease, of late years, has really been spoken and written about till people are quite sick of it, we will here mention only the more general or specially interesting observations.

The first thing worthy of note is, that many cases seemed to speak strongly for the contagiousness of the disease, and that the partisans of this theory increased among physicians; and that even the non-contagionists found themselves obliged to assume a family disposition for cholera.

On the other hand, we must not conceal the arguments on the other side, drawn first from the great number of persons attacked with cholérine (some of whom were quite void of fear,) though not so numerous as in our earlier epidemics; secondly, from the fact that the theatre of the earlier epidemic, namely, the

southern part of the town lying near the Elbe, was again attacked by preference this time, although, of course, there was not the slightest attempt at separation or stoppage of intercourse; and lastly, from the observation, that other diseases became modified by the choleric type, and were attended with spasms in the calves, iety, &c.

The first cases seemed again to occur among sailors. The lower classes and drunkards were especially attacked, and women more than men; but in women, from their well-known greater power of resistance, and the less injurious exciting causes, the disease was less malignant; so that of 215 fatal cases, 119 were males, and 96 females; while in this number there were only 27 who had not yet attained their tenth year.

This epidemic is distinguished from those of former years, not only by its greater mortality, but by the absence, even in many fatal cases, of some symptoms previously considered as characteristic. There was an occasional absence of the coldness and the *vox cholericæ*; the evacuations were often bilious, and the cramps slight; the blue tinge is said to have been less frequently observed, and the typhous stage came on less often. Lastly, the fatty spots upon the blood were seen only in the paralytic form. The dissections did not offer any differences of note from the earlier ones; the *trichocephalus dispar* has never been found here.

In the case of a woman in the hospital, treated with saline injections, the blood was found to be thin, the liver and the bile pale; in the left auricle there was a firm coagulum, and the cellular substance was emphysematous—an effect which was not produced by air injected at the same time.

Most of the attacks were preceded, as formerly, by diarrhoea, but with this difference, that it rarely lasted several days, and often only an hour or two.

Among single observations it deserves mention, that occasionally in the second stage of the disease, eruptions appeared, sometimes resembling nettlerash, sometimes scarlet fever, and sometimes roseola; that in some few cases violent cramps were observed in the muscles of the back; that in one patient, who ultimately got well, there was colliquation of the cornea on the sixth day; that in another patient, who was not a drunkard, a state came on resembling *delirium tremens*, which was cured by a treatment similar to the one employed in that disease; a couple of times the evacuations were like bloody serum; and once the attack was preceded by *gangrena senilis*. Prognosis left us in the lurch; and of the attempts at cure we cannot even say *meminisse jurabit*. The emetics

given at the commencement, even when they acted, which was far from being always the case, did not agree well. As to bleeding, from the beginning onwards, opinions were divided. (In the general hospital they employed cold baths, an infusion of *ipecaeuana*, with spirits of ammonia, or anodyne solution of camphor, and sometimes also an emetic. If the nausea continued, they gave the magistery of bismuth (the trisnitrate) and calomel. In the stage of reaction, besides general and local bleedings, they employed baths with cold effusion.)

Friction with ice was often the best remedy for the cramps in the calves, and effervescing draughts the best for the vomiting. A couple of cases of cholera were cured with the root of belladonna in half-grain doses every hour, with occasionally some calomel, and at other times quinine.

But let us hasten from this field where fewer laurels grow than weeping willows, and pass on to the measles, which, indeed, do not belong exclusively to 1837, as they occur from time to time even now (the end of April 1838.)

[To be concluded in our next.]

WESTMINSTER MEDICAL SOCIETY.

Saturday, 10th November, 1838.

MR. HALE THOMSON, PRESIDENT.

Different Forms of Ossification in the Heart.—Rheumatic Pericarditis.—Cases of Aphonia.

DR. C. B. WILLIAMS was elected an honorary member of the society; Mr. Streeter was named vice-president; and Dr. G. Bird was placed on the council.

Mr. Pettigrew, jun. commenced the proper business of the evening by relating the particulars of a *post-mortem* autopsy which he had witnessed at Glasgow. The case was that of a young woman, about 20 years old, who died of ossification of the aortic valves. The body was brought into the theatre; the history of the case was read; Dr. Cowan, the physician, gave a lecture on the subject, and prognosticated from the symptoms and physical signs that the valves of the aorta were ossified. The examination justified this prediction. Mr. P. wished to be informed whether this morbid change was not unusual at so early an age.

Dr. Johnson inquired whether the diseased valves were puckered, and what were the symptoms which induced Dr. Cowan to form his prognosis.

Mr. Pettigrew had not attended particularly to the reasonings of Dr. Cowan;

he merely remembered the result; and his cursory view of the diseased part did not enable him to say whether the valves were puckered or not.

Dr. C. B. Williams considered Mr. Pettigrew's question as interesting rather pathologically than clinically. His experience led him to conclude that these ossific depositions in the cardiac valves were not uncommon in adolescence. He considered these depositions to be amorphous; they were the result of chemical action rather than of any vital process. In the bony matter deposited on the sides of arteries, a decidedly lamellar arrangement could be detected; but in these valvular concretions a transverse incision exposed a crystalline formation.

Dr. Golding Bird's experiments confirmed the reasoning of Dr. Williams. He had had numerous opportunities of testing these concretions; and when slowly digested in acid, he had always found them to dissolve entirely, leaving no membranous relic behind.

Dr. Chowne had found these results of endocarditis present occasionally, the true ossific character, especially in the mitral valves, which in some animals, even in the normal state, had an osseous rim.

After a pause, Dr. G. Bird perceiving the discussion touching the ossification of the valves had ceased, related the case of a boy that he had seen in his dispensary practice. The boy had a severe attack of acute rheumatism, which had continued for some days, affecting several joints. The ordinary remedies were employed. One day he suddenly found himself relieved from all pain, and enabled to move about without inconvenience, and enjoyed a high flow of spirits. After three hours, however, violent symptoms of pericarditis supervened, the action of the heart and pulse was violently increased; a double *frottement* was obvious to the ear. The breathing was greatly accelerated, and the countenance became indicative of great anguish. He was then in course of treatment for pericarditis. The doctor asked to know if any member present had met with a similar case.

Dr. Johnson said, that whenever any such sudden cessation of symptoms occurred, the surgeon might expect a storm. A metastasis to the heart or stomach would infallibly occur. In the case of the boy, related by Dr. Bird, he thought most likely adhesion of the heart and pericardium would occur, or effusion of serum into the bag of the pericardium would first take place, and then be absorbed, and finally, adhesion be produced. The boy might live for many years.

Dr. C. B. Williams would be glad to know from Dr. Bird what were the stethoscopic signs during the interval be-

tween the departure of the acute rheumatic symptoms and the coming on of the violent pericarditis. He (Dr. W.) was of opinion that the heart was more involved in these diseases than was generally suspected. In the case of the boy, he had no doubt that the disease was in the heart at the moment of the cessation of the rheumatic pains, and remained latent till the accession of the violent paroxysm. The heart was often affected without giving any notice by pain or other obvious token, and often perpetrated much mischief before the vigilance of the medical practitioner was aroused.

Dr. Johnson inquired of Dr. Williams what was the disease present in the heart on these occasions?

Dr. Williams replied, endocarditis and pericarditis.

Dr. Johnson said, that in that case simple rheumatism was a much more serious thing than he had ever considered it. He did not believe that in the generality of cases of simple rheumatism the heart was affected. It was notorious that most of these attacks were removed by very simple treatment, and that no cardiac symptoms whatever could be detected. Violent and injudicious treatment, such as an excessive bleeding and the too frequent use of the warm-bath, by producing great debility, were circumstances not unlikely to bring on these inflammatory affections of the heart; but in ordinary cases, and with tolerably judicious treatment, he thought no such results need be anticipated.

Dr. C. B. Williams said, that with some people endocarditis and pericarditis were terrible words; but in his opinion their importance had been too much magnified, and the seriousness of acute rheumatism had been equally undervalued. He had often detected by physical signs the existence of carditis, when no symptom of any kind indicated it. In the great majority of rheumatic cases, he was of opinion that inflammation of the heart was co-existent with the presence of the malady in the muscular or synovial tissues.

Dr. Bird observed that the patient was not under his care, but under that of his colleague, Dr. Thomson; but as he lived nearer to the patient than Dr. T. he had been sent for on the accession of pericarditis. He had had no opportunity of examining the boy during the interlude of ease. He was disposed to coincide in opinion with Dr. Williams, that inflammation of the heart was a more common incident than was generally supposed.

Dr. Chowne thought that symptoms were often ascribed to endocarditis or pericarditis as a cause, when the real evil was a rheumatic affection of the arthradial membranes of the ribs, of the intercostal muscles, or of the diaphragm.

Mr. Pettigrew stated, that he had generally observed that a copious deposition of yellow or orange-coloured fat was a concomitant of the calcareous deposition between the folds of the serous membranes forming the cardiac valves.

Mr. Jones suggested that the seat of rheumatism was the neurilemma, not the proper tissue of the muscles.

Dr. Chowne, after a short pause in the discussion, inquired of the President if he had seen in the Westminster Hospital a case which had been related in the newspapers, of a policeman who had been struck suddenly with a suspension of articulation, which, after three days, he as suddenly recovered. He asked the question in reference to an opinion delivered by Dr. Beck, in his "Medical Jurisprudence;" who states, that no man who has the use of his tongue is dumb, unless he also be deaf.

The Chairman stated that he had seen the case cursorily. The man was not deaf; he could move the tongue perfectly; he could not apparently articulate a word. He made an incomprehensible noise in the throat whensoever he attempted to speak.

Dr. Johnson thought the policeman was an impostor.

Dr. Chowne was inclined to think that the case was not an imposture, because he had had a case somewhat similar. An aged woman, a patient at the Charing-Cross Hospital, had lost the power of articulating all but the words *yes* and *no*. He had no reason to suppose she was a cheat. She was treated with alteratives and tonics, and partially recovered. She was afterwards visited by a recurrence of the affection, was treated at another institution, and died. He had no opportunity of examining the body.

Dr. Bird suggested that the symptoms in Dr. Chowne's case might be explained by the analogy it bore to those cases where, in consequence of some affection of the brain, a sudden forgetting of one language and recollection of another occurred. He had seen a case in one of the Borough hospitals, where a Prussian, who had resided in England for many years, suddenly lost all memory of the English language, and spoke only German. Within twenty-four hours after this occurrence he died.

Dr. Johnson continued of opinion, that these cases of aphonia were genuine only when the motion of the tongue was impaired, which was the consequence of paralysis, or when accompanied with deafness. The motions of the tongue were conducted with great nicety, and might *apparently* be perfect when really the function was much disturbed. He recollected a case when he was a navy surgeon. It was that of the captain of a man-of-war, when going into action. Dr. J. and

the patient were standing on the quarter-deck, when suddenly the captain grasped the doctor's arm, and drew him into the cabin. There he wrote upon a sheet of paper the sentence, "Mr. Johnson, I have lost the power of speech." He was bled, and treated antiphlogistically, and recovered. It was a case of paralysis, though the *apparent* motion of the tongue existed. With regard to Dr. Chowne's patient, Dr. J. thought still she was an impostor; it might be difficult to assign a motive for her conduct, and her conduct might disarm suspicion; but so did that of the O'Keys, whom good Dr. Elliotson never suspected, till their feigning was discovered by Mr. Wakley.

Mr. Edwards related a case of aphonia occurring after poisoning by oxalic acid, when there was a loss of voice for eight days, without any other lesion of the voluntary power. The patient, a woman about 40 years of age, had not only lost vocalization, but could not even whisper. She was perfectly tractable in her conduct, and there was no appreciable motive for feigning. She had never shewn any symptoms of hysteria. The motion of the tongue and the power of swallowing were unimpaired.

Mr. Chinnock considered this case to be one of simple hysteria, of which kind he had seen hundreds. He concurred in opinion with Dr. Johnson, that there always existed impairment of the motion of the tongue in genuine aphonia. He had had a case of loss of speech in the son of a gentleman, and which lasted for two years. Dr. Lee, whose name would go down to posterity, attended with him. They consulted Sir Charles Bell. There was paralysis of the tongue; all the usual remedies were tried without any good result.

Dr. Chowne said that it was an easy thing to say that a case arose from hysteria or imposture, but not quite so easy to prove it. Facts were stubborn things, and could not be made to lose their individuality, or be marshalled into homogeneous regiments. His opinion of the genuineness of his patient's disease was not shaken by the reasonings he had heard. He was convinced there might be interruptions to volition and other nervous functions, independent of imposture, hysteria, or paralysis. Who had not witnessed temporary loss of vision, or of muscular power, dependent upon disorder of the digestive functions? If these effects could exist for short periods, they might also very probably exist for longer ones. He thought these instances constitute a class of facts that ought not to be dismissed so cavalierly. They were worthy of an especial study. He did not think the case of the Prussian related by Dr.

G. Bird, was at all similar to that of his patient, or in the least germane to the matter. The Prussian, it appeared, spoke his native language fluently, and conversed rationally with Dr. Bird. It was clear that there existed no aphonia, nor any sign of paralysis. What his disease was, an autopsy would have probably sufficiently explained. In his case at the Charing Cross Hospital there was nearly complete aphonia; but there was also perfect motion of the tongue; and this was a fact inconsistent with the principle laid down by Dr. Beck.

The clock striking ten, the meeting broke up. IDIOS.

PHYSICAL SOCIETY, GUY'S HOSPITAL.

November 17th, 1838.

MR. HILTON IN THE CHAIR.

Extirpation of the Cyst in Ovarian Dropsy.

MR. GORHAM read a paper on the propriety of extirpating the cyst in certain cases of ovarian dropsy. After giving a short historical account of the different modes of treating the disease at the present day, and enlarging upon the inefficiency of all the measures, whether topical or general, the author alluded to the operation for excision, spoken of by Dr. William Hunter more than half a century ago, and which he wished to advocate, inasmuch as it was the same, in every essential feature, as that which, more recently, had claimed for itself some appearance of originality. He then read the report of the operations performed by Messrs. King, Jeaffreson, and West, which had been published in the *Lancet**; and remarked, that they were all conducted in nearly the same manner. The method consisted in making a small incision through the abdominal integuments a little below the umbilicus, carefully dissecting, as in hernia, and opening the peritoneum on a director. The sac being exposed, a trocar was introduced, the cyst being prevented receding by forceps or tenaculum. The fluid was now evacuated, and the cyst drawn through the opening, which might be enlarged, according to circumstances. The substance by which it held connexion with the uterus was now cut through, a ligature applied to the uterine extremity, and returned into the abdomen. Sutures, adhesive plaister, cold lotions, foxglove, opium, and calomel, complete the treatment. The surgeons before mentioned advocated this plan because it had proved successful beyond expectation.

The objections that had been urged against the operation were then considered: and

first, that of wounding the peritoneum. The risk of peritonitis from local injury, the author stated, had been greatly exaggerated. Dr. Blundell's experiments went far to prove this. The author thought it fair to deduce from these as well as from many surgical operations, the following conclusion; viz. that the mere circumstance of making an incision into a peritoneum, previously uninfamed, is not so rash a proceeding as is generally supposed. The next objection was based on the probable existence of adhesions. These were a great barrier to success. When they existed in a minor degree, they might be overcome, and this was illustrated by cases. The frequency of adhesions has been greatly overrated. It was true that in many cases they existed before paracentesis; yet in by far the greater number it would appear that this operation was the cause of them. Their situation, and the constant practice of tapping, both favoured this opinion. The author considered the following inference a correct one. The existence of adhesion is by no means an unfrequent complication of ovarian dropsy, the cyst being glued to some viscus, in a few instances, more frequently, and with greater certainty to the walls of the abdomen, the cause of this latter being, in most instances, referrible to inflammation set up by the process of tapping.

The author here alluded to the diagnosis of adhesions.

Another objection to the operation was, that patients may live many years without any interference at all; but the operation may carry them off in a few hours. This was true. The same might be said of many other operations. Patients, for the most part, did not survive four years after the first tapping. Again, if the early period once passed by—if paracentesis was once performed—or inflammation once set up—the chances of success were reduced to a mere conjecture. Hence a rule—if excision be performed at all, let it be done early. This, however, was opposed to the opinion of Dr. Hamilton, who says that the operation is “unnecessary, if the disease be stationary.” Various other objections were combated by the author; and the paper concluded as follows:—“Considering how very many serious objections may be urged against paracentesis, why this should be in such repute, to the almost total exclusion of the mode by excision, I know not. As to the relief afforded by tapping, it is generally only temporary. ‘There are,’ says Dr. Bright, ‘I believe, few instances on record where this operation has apparently been followed by complete cure.’ This is saying very little in its favour, considering the many thousands of times it has been per-

* *Lancet*, Jan. 21, and Nov. 25, 1837.

formed. There are, too, several objections to it, which may be enumerated concisely as follows:—1st. Exhaustion may follow the too rapid evacuation of the fluid. 2d. Inflammation of the peritoneum may carry off the patient. 3dly. The sac refills, and requires repeated tapping. 4thly. There may be a many-celled encysted dropsy, or a too viscid fluid: and 5thly. Patients sink without any very evident cause. Scarcely more can be urged. Instead of thousands, few operations for excision have as yet been performed, and they have succeeded beyond expectation. As regards the rapid evacuation of fluid, the danger is as great in the one case as in the other. As to subsequent inflammation, the chances are reduced, on actual comparison, to a smaller amount after extirpation than tapping. No sac is left to refill; for through the incision into the abdomen we are enabled to take away a sac of considerable thickness, with many cells, whether the fluid be viscid or not."

At the conclusion of the paper an interesting debate took place, in which Drs. Loecek and Ashwell joined. The opinion of these gentlemen was, that much encouragement was held out for the performance of the operation; but that the greatest care was requisite in forming a diagnosis as to the existence of adhesions or solid malignant growths. A case was mentioned, in which Mr. Lizars, of Edinburgh, was so far deceived, as to operate when no disease existed; and in this instance, many experienced men who examined the patient, were equally deceived with the operator.

LONDON UNIVERSITY EXAMINATIONS.

To the Editor of the Medical Gazette.

SIR,

Is the leading article of your last number you object to so many subjects being required by the preliminary examination in Arts, *before* a student who wishes to take the degree of M.D. in the University of London can begin his medical education; and that from the "heterogeneous and irrelevant subjects," every art and science being insisted on but those that are medical, "such a plan cannot be carried into effect." Permit me to say that at least as much, perhaps something more, is required of every one who takes the same degree at Paris; and that the plan works very well, at least it did ten years ago, to my knowledge. There each student *must* take a Bachelor's degree in letters and in sciences. The examination for the first includes classics, rhetoric, ancient and modern geography, ancient and modern

history, and that of the middle ages, logic, metaphysics, and moral philosophy. That for the degree in sciences comprehends arithmetic, algebra, plane geometry, physics or natural philosophy, in which is required a competent knowledge of the properties of bodies, gravity, acoustics, optics, hydrostatics, pneumatics, heat, electricity, and magnetism; inorganic, vegetable, and animal chemistry, and lastly botany, including organography, physiology, and classifications, both sexual and natural.

In spite of this, however, great numbers take the degree of M.D., though it is true many are unsuccessful, especially for the degree in sciences, owing to the strictness of the examinations.

I am not surprised that you, in common with many others of all parties, should have advocated the establishment of a body with the power of granting degrees in this immense town, which possesses so many advantages as a school of practical medicine, from its many large and noble hospitals, and numerous dispensaries, where disease may be seen in all its forms. Although you designate the newly-established university at one time as democratic, and at another as aristocratic, it does not appear to me to have any political character at all, except, perhaps, its being too dependent upon the Secretary of State, whether whig or tory, for the time being; and I think it a pity that you should endeavour to treat it on political grounds. The charter was granted by the Crown, in compliance with an address of the House of Commons; and in a manner which I believe rather disappointed what you think the "favourite College," and so far from its "being made a leading point in the legislation of the Senate to assist various individuals connected with 'University College,' or that "the examiners will adapt themselves to a peculiar though small class of young men, the pupils of Gower Street College," the Senate have, as it appears to me, endeavoured to be strictly impartial. Indeed, with the Bishop of Chichester, as one of the Senate, who for so many years was the principal of King's College, it would not be very likely that any favouritism should be shewn to its rival establishment, which I have heard has been the complaining party. It is true that these two only are mentioned in the charter, because they were the only two schools at that time sufficiently organized; but if time is allowed to mature the plans, other medical schools, especially those attached to large hospitals, must be recognized; and I have no doubt that these schools will alter or extend their modes of teaching, to adapt them to the regulations of the University, just as they have already done in

various instances, to comply with the changes in education demanded by the College of Surgeons and the Apothecaries' Company.

As to the rivalry with Oxford and Cambridge, and the fear you entertain lest these students of medicine should be equal at the outset to the Bachelors of Arts in those universities, I cannot think that any members of those time-honoured seats of learning will view with jealousy the advancement of science and literature to which they themselves for so many ages have so largely contributed, or to the rewarding them by degrees in the capital of this empire, the only one in Europe hitherto without that power; nor can any reasonable objection be made to adding to the sound classical and mathematical education required in those universities, a knowledge of something modern, such as geography*, history, or languages, an addition which in all probability will sooner or later be made to the system of education at present pursued on the classic banks of the Cam and the Isis. It is well known that in compliance with the call of the public, such additions to mere Latin and Greek have been made, and are making, at most of the public schools.

There has been exhibited a good deal of impatience, and perhaps more ignorance, upon this subject. One of your correspondents, for instance (see GAZETTE for 29th September last), knowing a little, presumed more, and then jumped to the conclusion, that as there are no ostensible funds, there can be no exhibitions or scholarships at the new University; the fact being, as I am informed, that the Senate have a *carte blanche* in that respect, and the doubted scholarships have been now, and were then, regularly announced, at least for the degree in arts.

You object to the classical examinations not being in Celsus, or Aretæus and Hippocrates. Recollect the time and age at which these examinations are to take place—when the young men have just left school, and are only about to *begin* their medical studies. How can they be supposed to know any thing of the medical terms with which these authors abound, and what schools could teach them? The same regulations which you have so fallen foul upon have, it is well known, been sent round to a large number of the lecturers and hospital officers of London and elsewhere, to elicit their sentiments; and, without being a member of the Se-

nate, I am informed that the discrepancy of their sentiments with yours, and with each other, is most amusing. Like the old man in the fable, the senate will find it impossible to please every body; still, if some forbearance be shewn, there is little doubt but that the University will work beneficially when in full operation. Even at the time I am writing, a much larger number than was expected so early are being examined for their matriculation in arts alone. Relying upon your impartiality for inserting this,

Your obedient servant,

LAWSON CAPE, M.D.

4, Princes Street, Hanover Square,
November 5, 1838.

[The *professed* demands of knowledge in all these subjects are far less than the *actual*. The French students are as ignorant of every thing but the subjects immediately connected with their profession as any class of young men can be supposed to be. They are the last whom it would be desirable to make those of the London University imitate.—ED. GAZ.]

To the Editor of the Medical Gazette.

SIR,

In your leading article of last week, on London University Degrees, you have certainly fallen into an error, which it is desirable to set right, as your observations would be much to the point, were the premises upon which they are founded correct. You have assumed that candidates for the degree of Doctor, who have been five years in practice, are only to be examined upon subjects immediately connected with practice; but you omit to state that the candidate must *first take the degree of Bachelor of Medicine*, for which he is to be subjected to an examination in Celsus, Heberden's Commentaries, the various branches of Natural Philosophy, Anatomy, Physiology, Surgery, Chemistry, Medical Jurisprudence, Midwifery, the Diseases of Women and Children, Materia Medica, Therapeutics, Pathological Anatomy, and Practical Medicine. The aspiring practitioner will, therefore, be grievously disappointed if he expects to graduate on the easy terms that you have represented. He will have to *get up* much that he has forgotten, and which have proved of no service to him in practice. *Cum quibusdam aliis.*

Your obedient servant,

B.

November 17, 1838.

[We have thus the misfortune of appearing to one correspondent to have *over-rated*, and to another to have *under-rated*, the nature and extent of the examination.—ED. GAZ.]

* Head, in his amusing "Bubbles," says, "In after-life I entered a river of America, more than five times as broad as from Dover to Calais; and with respect to the Illissus, which had received in my mind such distorted importance, I will only say, that I have repeatedly walked across it in about twenty seconds, without wetting my ankles!"

BOTANICAL PRIZES.

To the Editor of the Medical Gazette.

SIR,

FROM the full and minute information which you supply on all matters interesting to the profession, and still more from your having exclusively all intelligence connected with Apothecaries' Hall, I presume it will not be an unacceptable communication if I forward you the names of the three young gentlemen who obtained the botanical prizes on the 9th of this month.

1st. Mr. Raper (Univer. Col.), the gold medal.

2nd. Mr. Robert P. Dodd (King's Col.), the silver medal, and 5 vols. books.

3rd. Mr. Boughton Kingdon (King's Col.), the books (5 vols.)

The books were, De Candolle's two works—*Organographie Végétale*, 2 vols., and *Physiologie Végétale*, 3 vols.

Mr. Ward, of Welclose Square, was the examiner.

I am induced to trouble you with this note, owing to the circumstance that you did not publish the names of the botanical prizemen last year, although it had previously been your practice to do so.

I am, sir,

Your obedient servant,

PHILOBOTANICUS.

[We did not publish the names last year, because they were not transmitted to us.—ED. GAZ.]

ON DIABETIC BLOOD.

By G. O. REES, M.D. F.G.S &c.*

THE experiments of some of the most careful and experienced chemists have failed to detect sugar in the blood of diabetic patients; and up to a very recent date it was supposed that the serum was free from contamination, even in the most virulent and lengthened cases of diabetes. Some late experiments, made by Mr. McGrigor, of Glasgow, seem to shew that sugar is present, not only in the blood and urine, but likewise in several secretions and excretions. The reactions obtained by that gentleman certainly rendered it very probable that sugar was present; but I am not aware that it has ever yet been separated, in its characteristic form, from the serum of diabetic blood; except by Ambrosiani, who relates a method by which he succeeded in extracting it in a crystallizable state. His process is as follows:—The blood is to be diluted with water; and boiled, in

order to separate as much as possible of the albumen and hæmotosine: the clear liquor is then filtered away, and precipitated by di-acetate of lead. The excess of lead is to be removed by a stream of sulphuretted hydrogen gas; and the precipitate being allowed to settle, the liquor is to be poured off, cleared by being boiled with white of egg, filtered, and evaporated to the consistence of a syrup: this, on being allowed to remain exposed to the air for some weeks, deposits crystals of diabetic sugar. By this process Ambrosiani asserts that he has succeeded in extracting sugar: and though I have not followed his process, yet I am inclined to consider it calculated to afford a satisfactory result; for I have observed that the presence of urea in the blood of diabetic patients interferes with the demonstration of the sugar; and the performance of this process would tend greatly to destroy that principle.

The method I have adopted will yield sugar of considerable purity; though it will not enable us to determine, with precision, the weight of the principle. The process is as follows:—

The mass of blood* is to be evaporated to dryness, over a water-bath; the dried mass to be comminuted, and digested for several hours in boiling water: the aqueous solution is to be filtered off, evaporated to dryness, and the dried residuum digested in alcohol of sp. gr. 0.825: the alcoholic solution so formed is to be filtered, or carefully poured off, evaporated to dryness, and the dry mass treated several times with rectified ether, which dissolves out urea, and also some fatty matter; leaving behind the sugar, in admixture with osmazome and chloride of sodium; this mass, on being dissolved in alcohol, and the solution allowed to evaporate spontaneously in a flat glass dish, affords mixed crystals of alkaline chloride and diabetic sugar; which are easily distinguishable from each other, and allow of being separated mechanically, by shaking them up in alcohol, when the chloride sinks; and the sugar, being principally collected above, may be removed, for examination, by careful use of the spatula: the alcohol must not, of course, be allowed to remain long in contact with the crystals, as it would re-dissolve them. It is a matter of surprise to me, that sugar has not been long ago detected in the blood of diabetic patients, though not separated from it; for the alcoholic extract of the serum, when mixed with water, will, after a few days, give off carbonic acid; which, in addition to the sweetish taste, and, I may add, syrupy smell of the evaporated alcoholic extract, is a sufficient evidence of the presence of sugar. I subjoin the analysis of 1000 grains of diabetic serum, obtained for me by

* From Guy's Hospital Reports, No. 7.

* 12 ounces were used in these experiments.

the kindness of Dr. Bright. The sp. gr. of this patient's urine was 1048; and the contents of the serum as follows:—

Water	908.50
Albumen (yielding traces of phosphate of lime and oxide of iron, on incineration)	80.35
Fatty matters	0.95
Diabetic sugar	1.80
Animal extractive, soluble in alcohol, urea	2.20
Albuminate of soda	0.80
Alkaline chloride, with traces of phosphate	4.40
Alkaline carbonate, and trace of sulphate, the results of incineration	
Loss	1.00
	<hr/> 1000.00

I should wish the proportion of diabetic sugar given here to be considered merely in the light of a close approximation; as it is impossible to separate it completely from impurity; and, moreover, the loss sustained by it during manipulation, which must be considerable, does not admit of estimation.

The alkaline salts contained a trace of an earthy phosphate in admixture; which is a curious fact, to which I have alluded in my paper on the analysis of the liquor amni.

It will be observed, on comparing this analysis with that of the serum of healthy blood, that we have here a great excess of matters soluble in alcohol, while the albuminate of soda is rather less than in health. The alkaline salts are also in very small proportion, being only 4.40 gr. in 1000 grains of serum, while in health they amount to from 7 to 8 grains per 1000.

I attribute my success in obtaining sugar, in its characteristic form, from diabetic blood, principally to the use of ether, which extracts from it the urea and fatty matter. I find that the ether of the shops of sp. gr. 0.754, which of course contains some alcohol in its composition, is an active solvent of urea, while it exerts no action on the diabetic sugar.

CORONERS' NEGLECT OF MEDICAL EVIDENCE.

To the Editor of the Medical Gazette.

SIR,

THE injustice to medical practitioners generally, in not being called upon oftener to give their evidence in a coroner's court, is sufficient to make them loudly complain, as shewn by Mr. Semple's letter in your last number. Within the last two

years many inquests have been holden in this neighbourhood, without medical evidence. The cases to which I refer were accidents to the body generally, more particularly those of the head, extensive burns, and sudden deaths. The reason assigned by the coroner is, that where the statement of the witnesses is clear, explaining the *moral* cause of death, the jury are satisfied without further inquiry; any trace of the *physical* cause is not called for; therefore a verdict of "accidental death" is returned, and the business of the court soon ended.

I could bring forward instances where the assemblage of coroner and jurymen has been a complete farce, but will content myself with relating only one:—

On Saturday, October 20th, I was sent for to a neighbouring village, to see a boy about seven years' old, who had been knocked down by the sails of a windmill. I found him quite insensible, with stertorous breathing, pulse scarcely perceptible, pupils dilated. An extensive fracture, with depression, was plainly felt over the lower portion of the left parietal bone; considerable blood issued from the ear, nose, and mouth. The only wound of the scalp was a small opening in the centre, large enough to admit the end of a probe. He died in four hours after the accident.

Now, sir, I staid at home on the day of the inquest, expecting to be summoned; but to my surprise no evidence was thought necessary. Calling at the house next day, I asked permission for a post-mortem examination; this was refused, not being required.

Every one must allow that Mr. Wakley deserves the thanks of the profession for his exertions in procuring the Act of 1836. But as Mr. Semple observes, "unless a compulsory clause is added, respecting medical men, the law is almost a dead letter."

Trusting that you will give publicity to this note, I remain, sir,

Your obedient servant,

JOHN COLLIER,

Member of the Royal College of Surgeons.
Towcester, Nov. 9th, 1838.

To the Editor of the Medical Gazette.

SIR,

THE appearance of Mr. Semple's letter, in the Gazette of the 3d inst., has given me considerable satisfaction, as it goes to prove that the evil it complains of is not confined to the provinces, as I had hoped, and the more extensive and glaring the evil, the nearer we may be approaching to a remedy.

Prior to the last enactment, which has raised the coroner's fees, and charged him

with the payment of witnesses and other expenses attendant on inquests, which are repaid him at each quarter session of the county, medical witnesses were paid by the overseer; and in this county, whether that be Cornwall or Cumberland, it matters not, we had no difficulty in obtaining our fees; but as soon as the last Act came into operation, coroners have availed themselves of every shift to evade calling medical witnesses, reasoning thus:—"If we call medical men, we must pay them, and suffer an outlay, (for which we gain no advantage,) till the magistrates shall have passed our accounts; it is, therefore, our interest to keep our money in our pockets, so, *valere medici*:" but such reasoning looks a little like dishonesty, because these gentlemen are paid an increase of salary, to remunerate them for the short time they advance their money; all tampering with, and evading the demands of, justice are calculated to bring a useful institution into contempt, and the community will not be slow in concluding that they pay to keep up, as Mr. Semple expresses it, "an expensive farce." I go no further, and submit that the coroner is, by his oath, bound *to get at*, as far as in him lies, the truth, the *whole truth*, and nothing but the truth, as the witnesses are to *speak* the same, and that if he suffer any thing to be kept back, he may be considered, in a moral point of view, guilty of —

I am, sir,

Your obedient servant,

CHARLES HOPKINS.

Nov. 10, 1838.

STATISTICS

OF THE

COBURG LYING-IN SOCIETY OF CHELTENHAM.

To the Editor of the Medical Gazette.

SIR,

HAVING had, during the past year, the surgical superintendence of the Coburg Lying-in Society of this town, I have taken the trouble to register various facts, which have supplied me with materials for a statistical account, which may not be altogether devoid of interest. If you will admit a communication of this kind in your columns, I shall feel obliged by its insertion.

The Coburg Society was instituted immediately after the death of the Princess Charlotte, and holds its annual meetings on the sixth day of November. Its objects are, to furnish obstetric aid to indigent married women, and afford them relief by

money, linen, &c. during the month. It is a rule, that "No woman is to receive relief from this charity for her first child, except in cases of extreme distress."

From November 6, 1837, to November 6, 1838, 216 women were delivered, and no death occurred either during the labour or the month succeeding. No case requiring embryotomy, and no placental presentation, occurred. The forceps was applied once in a case of impaction. The vectis was never used, nor a single dose of ergot administered. There were two presentations of the superior extremity at full gestation, and two about the sixth month.

In 167 cases the sex was noted:—Males, 87; females, 80.

In 193 cases inquiry was made as to the number of times the individual had been pregnant (early cases of abortion not being taken into the account.)

Of these 1 was the 1st pregnancy.

15	2d.

The infrequency of deaths among parturient females in this place is worthy of remark. I have been surgeon to this society for two years, and no death has occurred within this period; and the same may be said of two similar small institutions in this place, which together relieve about 100 annually. I believe this is mainly owing to the healthy condition of the lower classes, who are the immediate descendants of agricultural labourers, are employed in no manufactories, and among whom the extreme of poverty and destitution is mitigated, if not prevented, by the munificence of the wealthy.

I am, sir,

Your obedient servant,

HENRY COLES.

Cheltenham, Nov. 13, 1838.

CRYSTALS IN THE HUMAN INTESTINES.

THE individual in whom they occurred was a male, aged about forty, who died of pleuro-pneumonia and gastritis, having been admitted into hospital only a few days previous. On examining the intestinal canal, the contents of the colon appeared of a lighter colour than usual, and more fluid. I observed some very small bodies suspended in the *fæces*, which on removing and rubbing between my fingers proved to be solids; on drying and examining them with a lens, I found that they were perfectly regular crystals, (although somewhat less than the third of a line in length :) they were in considerable numbers, but so very minute that it required a long time and a good deal of trouble to separate a sufficient number to allow of a chemical examination.

The colour of these crystals was white, some however were yellowish on the sur-

face, being stained by the contents of the colon. Their figure was a slender four-sided prism, terminated by four-sided pyramids, and the edges and angles were exceedingly perfect. On analysis, Dr. Apjohn found them to be composed of the ammoniaco-magnesian phosphate, or the triple phosphate, as it is commonly called. The colon was the only part of the intestinal tract in which I succeeded in detecting them, and there existed no ulceration in any part of the mucous membrane.

The four-sided prism does not appear to be the most common figure of the crystals of the triple phosphate; when they occur in the urinary bladder they are usually short three-sided prisms, terminated by three or six-sided pyramids.

The composition of the crystals found by Professor Schoenlein was very different from these. Müller does not mention the composition of those which fell under his observation; but as they were on one occasion long four-sided prisms it is not likely that they consisted of the ammoniaco-magnesian phosphate. This compound, too, seems to form the principal ingredient in most of the concretions which have been examined from the intestines of quadrupeds, in whom they are not very uncommon. Fourcroy and Vauquelin found some from the horse to be composed of the triple phosphate; and Dr. Marcet says, that all the specimens which he had an opportunity of examining consisted entirely of the same salt.

The concretions to which I have alluded as having been met with in the human intestines in these countries (which are described by Dr. Mouro, in his *Morbid Anatomy*), have been noticed only in Scotland, and consisted almost altogether of the beards of the oat (which forms so prominent a part of the food of the lower orders in that part of the United Kingdom), matted together and cemented by animal matter, with or without a central nucleus; some of these alvine concretions, however, had a coating of crystals of the triple phosphate, others of phosphate of lime mixed with animal matter.

In a recent number of the *Dublin Medical Journal*, Dr. Harrison has given an account of some minute prismatic crystals, detected by him on the peritoneum of subjects brought to the dissecting-room, which, on analysis by Dr. Apjohn, was found to be composed of the ammoniaco-magnesian phosphate.

But I believe the case which I have given, is the first in which separate and regular crystals have been noticed in these countries, in the contents of the human intestines. And though much importance does not attach to an individual case, yet, as far as a single one can, it will help to prove that Dr. Schoenlein's assertion is

too sweeping, viz., "that the presence of these bodies in the intestinal discharge may be considered as an important diagnostic mark of typhus fever."—*Dublin Journal of Medical Science*, November 1838.

ON THE RESPIRATION AND DEGLUTITION OF THE BOA CONSTRICTOR.

DR. ROBERTSON, on Monday, Sept. 17th, presented to the Institute some new observations on the respiration and deglutition of the boa constrictors, at present exhibiting at Paris. These enormous serpents swallow several large live fowls, one after the other, at a meal. During the repast, which lasts half an hour or more, the throat continues greatly distended, and all communication between the nostrils (through which the reptile usually breathes) and the lungs is completely shut out; but, by an admirable provision of nature, the creature protrudes the orifice of its windpipe, from between the branches of the lower jaw, quite out of its mouth, to the extent of an inch, and at least three inches beyond its usual situation. The throat being distended to its utmost stretch by the fowl or rabbit in the œsophagus, the glottis is seen protruding between the branches of the lower jaw and the skin of the throat; and the protrusion is greater in proportion as the object in the act of being swallowed is of a large size. Every half minute, more or less, the orifice of the windpipe is opened to nearly half an inch in diameter, and a gush of air, like that from a pair of bellows, issues out; and, fresh air being immediately afterwards taken in, the glottis is again closed by the sphincter muscles till the next expiration, and so on alternately.—*Galignani's Messenger*.

OMNIUM GATHERUM.

THE following extraordinary jumble appears as one continuous article in a recent number of the Boston Medical Journal:—

"*Medical Miscellany*.—The cholera has re-appeared at Naples.—Of the 80,000 Russians who marched into Circassia, a few only have returned, and they were so severely attacked with ophthalmia that most of them are blind and rendered incapable of service.—A catalogue of the Louisville Medical Institute has been received, shewing one hundred students, their first term.—Dr. Bartlett's address before the Phrenological Society is greatly admired.—Dr. Rockwell, Health Officer of New York, has been nominated to the Senate, notwithstanding some have said he lacks official capacity. He is unquestionably a first-rate man for the place, as his past services testify.—At the last

accounts, Dr. Warren, of Boston, now travelling in Europe, was on his way to Italy.—The Vermont Mercury says there have been only four deaths by smallpox in Woodstock. We do not see how this fact in any manner contradicts the statements in the letter from Woodstock, inserted in this journal for January 17th, although apparently published for that purpose."

LECTURES ON SURGERY,

DELIVERED AT ST. THOMAS'S
HOSPITAL,

BY THE LATE MR. CLINE.

(Concluded.)

LECTURE X.

Circumstances requiring Amputation—Amputation below the Knee—above the Knee—of the Wrist—of the Os Humeri—of the Shoulder-joint—Bandages for the Head and Trunk—Bandages for the Extremities.

Circumstances requiring amputation.—Before we enter upon the amputations of different parts of the body, we shall say something of the diseases requiring the operation, and the state of the constitution in which it is most favourably performed.

Sometimes there is necessity to remove a part, from being in an incurable and diseased state, to put a stop to inconveniences arising therefrom. The operation is often required on the smaller joints when the life is not in danger. Also, injuries suddenly inflicted on parts, as compound fractures from common accidents, or sometimes from gun-shot wounds, in either of which the operation is sometimes required almost immediately. Sometimes there is a great difficulty of determining whether the operation should be performed or not. When there is a great destruction of parts, without doubt the operation should be performed immediately, as it will give the patient a better chance of recovery. It is the same with any of the larger joints. In exposure of the cavity of large joints, as the knee and ankle, the danger which would probably arise from such accidents would be greater than from amputation of the limb, though the patient might be in perfect health. The patient would probably die before

suppuration could take place; so much would the constitution be deranged by the violence of the symptoms. When considerable injury has happened, though we know from experience what the progress of the disease will be, a good deal of mischief will often be prevented by the immediate operation. It is found, from experience, that in a state of good health, and when the constitution is strong, it is not the most favourable time for performing any capital operation, more especially amputation. When a large part is to be removed, the violence done to such a constitution is greater than to another which is previously exhausted by disease; therefore, amputations performed immediately after accidents on healthy subjects do not succeed so frequently as in those debilitated by long disease. Thus, in cases of diseased joints or diseased bones, very few die in consequence of the operation, when compared with those in consequence of compound fractures, or gun-shot wounds, where the operation is almost immediately performed. In some cases the operation will be less dangerous than for the injured parts to remain; but it is only in those cases where the mischief is exceedingly great that we should operate immediately. It is almost impossible to point out the precise time at which the operation should be performed—when it should be performed immediately, or when it should be delayed for some time: this is to be left to the discretion of the surgeon, and is only to be acquired by long experience.

Mortification is also spoken of as a complaint requiring the operation immediately, even when independent of any injury, which is not unfrequent in old people. There was an idea formerly that the mortification was spread by the dead part being in contact with the living; therefore it used to be the practice as soon as mortification had taken place to remove all the dead part. From the bad success

of operations performed in this way, practitioners afterwards waited till a more favourable opportunity arrived, when the mortification ceased to spread, which was found to be the more advantageous, and oftener attended with success. When we consider the manner in which mortification takes place, the reason will be obvious. It is always preceded by inflammation, and it much oftener arises in those constitutions which are weak than in others. It rarely happens to one in good health, though the inflammation is very violent. It is particularly the case with patients who have general dropsy, or who are anasarous: small incisions through the skin very frequently, from the slight inflammation which follows, are attended with mortification of the part. Mortification seems to arise from such increased action taking place as the part is incapable of supporting; this must sooner happen in a part that is weak than a part that is strong. Under extreme violence, in healthy constitutions, when the inflammation has been exceedingly great, mortifications now and then happen; however, this is but rare. As inflammation is the cause of mortification, it must be increased by whatever produces it; therefore, in such a state, the performing the operation would be most unfavourable for the patient. When, instead of performing this operation, the surgeon waits till a favourable change takes place in the constitution (which might partly be effected by proper regimen and medicine), it may then become capable of sustaining the inflammation which is produced, and mortification be thus prevented. A part that is mortified will completely separate if left to itself; even a dead portion of bone will separate in some weeks; therefore it will be better not to operate at all. Of this I have known several instances where mortification has extended from the feet upwards to a little below the knee, where, in the space of five or six weeks, the dead parts have completely separated, and the patients have done well. By thus letting parts separate of themselves, a very painful operation is avoided, as well as the consequent inflammation which must arise from the operation. The danger of this operation, besides being proportioned to the constitution, is also proportioned to the size of the part to be removed. Thus the loss of a hand is attended with less violence to the constitution than the loss of a foot, or an arm less than a leg. When the part to be removed is not large, and the patient has been previously lowered by disease, there are hopes of success. The reduction of the constitution should, however, be limited, for the patient may become so

weak as to make the operation very dangerous, more especially if there should happen any unfavourable hæmorrhage, as the loss of even eight or ten ounces of blood; therefore we should not suffer the patient to go on too great a length of time. When they have been a good deal weakened by disease, the alteration which takes place almost immediately on the diseased parts being removed, is surprising, which shews that the whole of the complaint arose from the constitution sympathizing with the diseased part.

Those parts are most favourable for operations where the most muscles are situated, being very vascular, therefore more favourable for healing. A joint is always unfavourable, as cartilage will not granulate, and ligament always granulates very unfavourably: the proportionate number of vessels being but few, therefore we avoid amputation in these situations. Besides which, inflammation arising in large joints produces very considerable violence to the constitution; but in small joints amputation may be performed without any particular inconvenience, for you may easily preserve skin enough to be extended over the surface; union will take place; and where the joint is small it does not injure the constitution. In one joint rather large—viz. that of the wrist—the operation has been often performed with success: that being formed by the radius and superior part of the metatarsal bones, you may leave integuments enough to come over the extremities of the bones. In the toes and fingers, amputation at the joint is easier than sawing through the bone. In all amputations we should endeavour to save as much skin as possible, to cover the extremity of the part. This is a great improvement; it was formerly the practice to cut directly through the part; the whole breadth of the stump was exposed, consequently greater inflammation arose, and more violent effects to the constitution: it was also very unfavourable for healing. The stump, under these circumstances, being often three or four months in healing, and after it has healed the cicatrix is very liable to ulcerate.

Mr. Cheselden first made the improvement of *double incision*, whereby a good deal of skin was brought over the large surface, but not enough left to cover the extremity. Another mode of operating was to leave a *flap*; in which, I believe, there is greater violence done to the constitution. A piece of lint was interposed, and both surfaces allowed to suppurate, which was unfavourable. But since that, another considerable improvement has been made by Mr. Allanson, of Liverpool—

viz. extending the double incision higher up than usual, carrying it round the cellular membrane and muscles, so as to draw it further from the bone; and, instead of interposing any lint between the extremities, laying it over the surface, which makes a larger portion adhere by the first intention; and the more it adheres in this way, the less is the danger of symptomatic fever, and there is scarcely any cicatrix. This has been very generally adopted, and found very successful. The operation, however, will be more successful in some states of the constitution than in others. When that is so far in a healthy state as to be capable of producing union by the first intention, there is little symptomatic fever, union is soon produced, and the stump healed in a short time; but this is very far from being the case in some scrofulous and scorbutic constitutions. In this mode of operating, under some circumstances, accumulations of matter take place between the skin and extremity of the stump, so as to be unfavourably lodged, through the skin forming sinuses very unfavourable for healing; this will happen sometimes, though very rarely. If we consider the operation in a general point of view, it is certainly more favourable than any of the former, therefore should be generally adopted. Before we begin this operation the vessels should be restrained from bleeding, for which we have tourniquets, which are variously constructed; they may be either a simple ligature with a stick, or a screw tourniquet. The screw tourniquet is very convenient, for being once fixed, it remains of the same tightness, without the necessity of holding it; therefore particularly useful where a number of assistants are not at hand. But in private practice, where you have assistants enough, the common stick tourniquet is more convenient, more readily fixed on the part, and more readily tightened. In tightening and slackening the screw tourniquet several turns are necessary; hence an unnecessary quantity of blood is lost.

In the arm, the middle of the *os humeri* is most convenient for applying the tourniquet; the pressure being made on the inner side of the *biceps* muscle, where the artery is descending. If you are under the necessity of compressing it higher up, it should be under the tendon of the *pectoralis major*; or if you amputate at the shoulder-joint, you should place it under the clavicle, on the first rib. During the time of pressure the shoulder should be lowered a little to bring the clavicle downward, to have a more perfect command of the vessel.

In the lower extremity the pressure

should be made on the inner side of the thigh, just above the perforation of the tendon of the *abductor* muscle, where the artery is situated close upon the bone. If amputation is necessary higher up, then the pressure should be made on the pubes, where it is passing under *Poupart's* ligament.

The instruments required in this operation are generally in one case. A large knife to amputate the lower limbs, which may be either straight or curved: if much bent it is inconvenient, as all instruments cut by drawing them along the surface, not by making pressure. The sharpest instrument cuts on the same principle as a saw. If slightly bent it is convenient, because it is applied to a larger surface; but a straight knife will cut through quicker. If the limb is sound, and you require a small knife, the bending of it would be rather inconvenient; therefore a straight knife is preferable. A catlin is a small knife to be introduced between the bones, to divide the *interosseous* ligament, and those muscles and integuments which you have not perfect command of in the circular incision. A saw should consist of a blade set in a frame, which may be tightened by a screw. If the blade is not kept firmly fixed, the teeth are continually hitching on the bone, and you cannot saw so as to form a smooth surface; the saw is every now and then stopped. It should be always kept unscrewed.

The *tenant* saw is of a better construction than the former, having a stronger back, which keeps the blade perfectly fixed. It should be exceedingly well tempered, the steel well hardened; as it is to cut through the solid substance of bone, the teeth are very easily turned: also, the teeth should be very small. When there are large interstices between the teeth, it cuts very roughly through the bone, and when nearly through generally splinters it. When such a splinter happens it should be pinched off, otherwise it will very much irritate the soft parts which are brought over the ends of the bone.

The *metacarpal* saw, the blade of which is easily introduced between the bones, is also made with a screw to tighten it before it is used. We have also a *tenaculum* and needles.

In amputation of the toes it is convenient to have an assistant holding the other toes apart, by a piece of tape carried round them: here we may amputate at the joint. For this purpose we first make the circular incision a little below, and not into the joint, by carrying the knife laterally, not only on account of the small process of bone going over, but the greater firmness of ligament laterally than

superiorly and inferiorly. Sometimes a part of the metatarsal bones is diseased, so as to require removal. This may be done by making an incision above and below, saving the integuments completely to cover the bone. Here it is improper to take it off at the joint, because the basis of the metatarsal bones forms the common cavity. We make an incision above, and carry it on one side the toe. Let the incision be extended to the same part on the other side of the toe, down to the under part of the bone, dividing the flexor and extensor tendons; then introduce the saw between the bones. The integuments above and below not being removed, may be brought in contact by slips of plaster. The wound soon heals, with very little deformity. When the tarsal bones become diseased, and an operation is necessary, it will be proper to remove the foot, or greater part of it; for the tarsal bones are very complicated, and by removing one you expose a large surface, so that there would be little probability of saving the part. If you could take off the whole of the foot, leaving the os calcis and astragalus in a sound state, it would be very convenient. Supposing the tarsal bones situated forward were diseased, a circular incision might be carried round, leaving sufficient integuments between the os naviculare and cuboides.

The pollex pedis should be cautiously amputated, being a chief support to the foot; hence the patient always halts afterwards.

The ankle-joint is too large to think of amputating there; but there is an operation which has been performed by O'Halloran and White and some others, a little above the ankle. This has been very much recommended by some writers, and having an artificial foot, and preserving the joint of the knee; but it requires a great deal of nicety in the construction of such an instrument; and though it may be constructed so well that patients may walk on it for some time, yet I doubt whether it can be so well constructed for a man who is obliged to bear the pressure on so small a surface, and he would be in a much more comfortable state if the limb were amputated higher up. Also, a stump at this part is more unfavourable for healing than higher up, where there is more muscular substance; and the lower part seems to excite greater violence to the constitution.

I have had an opportunity of seeing one of Mr. White's patients, which was a man not under the necessity of being much on his limbs. He had an instrument made according to Mr. White's directions, but he preferred the pressure on the knee to the artificial foot.

Amputation below the knee.—The surgeon should be placed between the patient's legs, as being more favourable to saw through both bones at once. The length of the stump in the adult should be about a hand's breadth below the knee. To make it of that length the incision should be begun about two inches below where you intend to cut through the bone; this will be varied according to the diameter of the limb; as that is large, you should allow a greater length of integuments. We first make a circular incision through the integuments, whether at once or twice being very immaterial. Having done this, an assistant should draw up the integuments while you separate the cellular membrane. The adhesion is greatest at the bottom. The integuments should be still kept drawn up. Next we cut through the loose muscles, in doing which the knife should be carried a little obliquely upwards: the muscles between the bones to be divided by the catlin. Laying the saw directly on both bones, we proceed sawing very slowly and lightly when nearly through the bone, to prevent its being splintered; then secure as many arteries as possible, without slackening the tourniquet; here there are generally three, the anterior and posterior tibial, and interosseal: afterwards draw the integuments over the edges near together by adhesive plaster, to unite by the first intention. Mr. Anson directs the edges to be brought perpendicularly, so that if union does not take place by the first intention there is a way for the discharge of matter; if made a little obliquely it will be full as well; you will have a sufficient opening, besides the advantage of having the extremities of the vessels directly opposite to the opening, so that the ligatures are readily removed, there is no sinus, and greater probability of union by the first intention, and the ligatures are drawn out in a direct line. Also, if there should arise a hæmorrhage after the operation, you may more easily get at the vessels, especially when union has been in part effected.

Amputation above the knee is easier than the former; you can more readily separate the integuments and muscles, beginning near the joint to preserve the integuments. The first incision separates the integuments, admitting of their being drawn up some way. In some parts they will adhere more than in others, as where the fascia is situated close on the skin and the extensor tendons. The next incision separates these; then you are to carry it through those muscles situated loosely on the thigh: this will give more room when the muscles are retracting. You then make an oblique incision through the re-

maining muscles, while an assistant is drawing up the integuments; you next saw through the bone, making long strokes, and not bearing hard on the saw (every surgeon should practice sawing); the integuments are to be brought together as near as possible.

Sometimes, where the patient is much reduced, the small vessels appear incapable of contracting, and we have a hæmorrhage from the whole surface; in such patients it is better to support the vessels on the extremity of the stump by a roller.

There has been an amputation at the hip-joint, but the patient died soon afterwards: this is too great a violence for the constitution to support*.

Amputation of the fingers and metacarpal bones is performed in the same manner as for the toes, &c.

Of the wrist.—In this you have only to cut through the integuments, tendons, and ligaments of the joints, beginning the incision at the basis of the metacarpal bones, leaving sufficient integuments to cover the joint, about an inch below the styloid process of the radius; then the integuments being drawn backward, and the tendons divided, the incision is to be made at the extremity of the radius. The most convenient part to cut into the joint will be below the styloid process of the radius; having carried the knife through at that part, getting into the joint, you can easily separate the hand.

Amputation of the fore-arm is performed in the same manner as that of the leg, standing also on the same side of the limb to have command of both bones, &c.

Of the os humeri.—It will be more convenient to stand on the outside, that your left hand may be above the incision.

Of the shoulder-joint.—This is a nice operation, on account of the situation of the axillary artery; which, from its size, and being so near the heart, affords a profuse hæmorrhage; therefore it would be safest to secure this vessel in the first part of the operation. This is most safely to be done by laying the artery bare by an incision in the axilla first, just under the pectoral muscle. A plexus of nerves accompanies this artery, and it therefore requires some attention to distinguish the nerve from the vessel, which is very readily done in the living subject. Including the nerve in the ligature would be productive of extreme pain. This is an instance in which the flap operation will be more convenient than any other. We should leave enough flap to cover the wound, beginning the incision from the bottom of the deltoid

muscle, extending it upwards quite to the shoulder-joint. This is done by pinching up the muscles, &c. with the left hand, and carrying the incision up to the acromion process. We next make a circular incision, which done, it is better to take the os humeri into your own possession, to have perfect command of it, and to bring it out of the articulation. A flap is to be left to cover the bone, which should be confined by adhesive plaster. Union will take place very readily provided the subject is in tolerable health, and there is no disease of the scapula. It has been performed successfully.

Bandages.—The forms of these are various, being adapted to different purposes, as well as different parts of the body. They are better if made of linen cloth that has been worn. For particular purposes they are made of cotton or flannel. The application of these, more especially when they depend upon rolling, requires a degree of dexterity. Bandages are either simple or compound—simple, when composed of one piece of linen—compound, when of several. They have various names from the parts they are applied to, and the intention they are to answer. Of simple bandages, that which is commonly used is a long slip of linen, rolled up, called a single headed roller; when rolled up at each end it is called double headed. According to their manner of application they have different names; as the *circular*, when applied immediately in circular turns; the *spiral*, when carried obliquely upward or downward, on account of the different thickness of parts. The *rampant* is when these spiral turns are much increased, so as to leave parts uncovered for the purpose of applying dressings. The *reversed* turn is when the roller is brought back again, by which we are enabled to apply the bandage with greater smoothness. For the head we have a great number of bandages, which may be varied according to circumstances and convenience; the most simple of these is by taking a handkerchief, or napkin, of which there are two sorts, called the *simple* and *grand kerchief*—the simple, when the handkerchief is folded triangularly, placing the longer side of the angle on the forehead, bringing the ends of the handkerchief round the occiput, where it may be tied, or if long enough brought round to the forehead. The *grand kerchief* is by folding the handkerchief in an oblong form, being one side within, about a hand's breadth of the other; the middle of which is to be placed on the summit of the head; being thus folded it makes six angles or ends, the two middle of which are to be brought under the chin, and there tied, or pinned;

* The success which has attended Mr. Guthrie's, and other cases of amputation at the hip-joint, may be considered to have established it as one of the operations of surgery.—C.

the portion which is suffered to hang down the face may be turned back on the forehead, and the two ends carried back towards the occiput, where they are to be pinned, and the two posterior ends are to be brought to the forehead, and tied or pinned. We have two bandages applied to the head, called *slings*; one with four, and the other with six heads; they are very convenient for retaining dressings, and are very cool in summer; the former is fastened to the forehead and occiput; the latter under the chin.

The *uniting bandage* consists of a roller, which should be two or three yards long, rolled up with a double head, and a slit in the middle, which may be applied to the head or any of the extremities.

For the eyes, we have the *monoculus* and *binoculus*, simple headed rollers about six yards in length, carried in oblique turns over the eye, round the forehead.

For the nose, a sling with four heads, made as the other slings, only with an aperture in the middle, is convenient in fractures of the os nasi.

For the upper lip, a sling with four heads is of use in the hare-lip, after the operation. Mr. Dent, of Ireland, has contrived one composed of three pieces of tape united to each other, and is intended as a substitute for pins or needles.

For the lower jaw, we have a sling, as other bandages, only as a slit for the chin, for retaining dressings.

For the shoulder we have various bandages: as the *spica simplex* and *duplex*, recommended in fractures of the clavicle—when over one shoulder, it is called *simplex*; when over both, *duplex*: that part which appears to be raised in a fractured clavicle, is, in fact, in its situation, and only appears so in consequence of the depression of the other; therefore applications to keep it down are improper. The shoulder should be carried backward, and supported so by a sling and a roller, about five yards, applied in form of a figure of 8, going first under the axilla, the shoulders being held back, then over the shoulder, and obliquely across the back and over the opposite shoulder. In children the bones are perfectly manageable by this bandage, but in the adult we can hardly make it sufficiently tight (especially in a fat person) without a permanent deformity. Mr. Haighton has contrived one for keeping the shoulders back, which consists of two pieces, each of which has a loop, through which one end of the bandage slides in; to the looped part is fixed a small strap. The arm is placed through the loop; there is a pad placed under the buckle as a defence from its pressure. Mr. Hay, of Leeds, contrived another.

For the chest we have several: the sling with four heads, also the double T bandage; another called *napkin and scapular*, consisting of one broad part which is to go round the chest, another piece fastened to it, with a slit in the middle to receive the head, which prevents its slipping down. For fractured ribs it will be better to apply a double-headed roller of flannel or calico, which is better than linen, about eight or ten yards in length, and about a hand's breadth. For umbilical or ventral herniæ, trusses should be applied for an adult, made with steel springs; in children a piece of cork, cut the size of the aperture, and dipped in sealing-wax, to give it a smooth surface, and confined by sticking-plaster.

After the operation of *paracentesis*, if the viscera want support, we apply a flannel roller 8 or 10 yards in length, which is better than linen, being softer.

A convenient bandage for the scrotum is the bag truss: the bag receives the scrotum, a strap goes round the abdomen, and two straps pass under the thighs.

There is one described for the perineum, called *knotted*, about 10 yards in length, carried alternately over each shoulder and hip, and crossing, forming a knot in *perinaeo*; it was used to restrain hæmorrhage in cutting for the stone, but the vessels are too deep seated to be thus compressed.

Application of a truss to the groin is a process in which there is a great deal of nicety to make it sit well on the part; and to have the steel so tempered as to make strong pressure and not give pain, is often very difficult to accomplish. The patient at first will be uneasy, but the pressure should not be so great as to inflame or excoriate the part. The pad should not be very broad, and should take the same degree of obliquity as Poupart's ligament. We should find the situation of the ring by feeling for the spinous process of the pubes; a little above, obliquely and outward, is the ring; still further above, is the orifice of the sac, upon which the middle and most prominent part of the pad should be placed in the common serotal hernia. Being thus placed, and the patient desired to cough, no descent will take place. The pad should be immediately over the orifice of the sac, and the spring carried round immediately under the edge of the crista of the ilcum; if lower, the *glutæi* muscles will displace it. If there should be that species of hernia where the sac is situated on the inner side of the epigastric artery, then it would be absolutely necessary to apply the pad on the orifice of the ring. The length of the spring should be regulated entirely by the size of the patient; it should not be long enough to extend beyond the spine; if it

does, the edge presses on the glutæi muscles, and every time they are in action will move the pad. Sometimes it is necessary to bend the pad inwards, to make the pressure complete: this will vary according to the form of the patient. A compress of fine flannel may be put under the pad, to prevent excoriation, and the part now and then washed with cold water, &c. This is not likely to happen if the pad is put properly, so as not to press on the bones. The truss should be worn night and day. After wearing a truss some time, there will be more danger of strangulation in case of protrusion than before, the mouth of the sac being more contracted; therefore it should be continued for some time after the patient is apparently well.

Bandage for the penis.—After any operation, the fluids have a tendency to gravitation. If the penis hang down, the inflammation will be kept up; it therefore should be confined to the abdomen by a narrow roller or fillet, fastened to a circular one previously passed round the abdomen.

Bandages for the extremities.—First, for fractures of the os humeri: if a simple fracture, two single-headed rollers will suffice, 5 or 6 yards in length. Having reduced it, &c., begin to roll the arm immediately under the fracture, carrying it in two or three circular turns directly round, which supports it; then in moderate spiral turns, either ascending or descending, so as to cover the arm. After this, the splints are applied; in a simple fracture, pasteboard will do. Short splints are improper, as the smaller the surface the more moveable the bones. These splints should be confined by a second roller, which goes in a spiral manner contrary to the first, and thus corrects the twisting of the muscles, &c.

When a simple fracture is near a joint, as the condyles of the os humeri or olecranon of the ulna, the limb should be kept steady, and in a bent position; a single splint of pasteboard should be applied.

When inflammation is abated, the joint should be gently moved about every second or third day, to prevent ankylosis.

For stumps a cross cloth is used to retain the dressings; also, it is proper to pass a circular roller to confine the integuments and prevent their retraction, previous to which they should be drawn forward by an assistant.

In fractures of the thigh the many-tailed bandage is more convenient. For-

merly they kept the limb quite straight, in which case the bones used to ride one over the other, the limb became shortened, and the patient suffered much pain; afterwards the practice of bending the limb was adopted; it is a better position, yet is subject to one inconvenience; it is easy to the patient during the cure, but afterwards there is a twist; the knee and foot are turned out, and this causes him to halt, to avoid which we may lay it in a position between both, viz. by bending the leg, while at the same time it is not out of the line of the body; in that position the foot should be steadied and fastened by a roller to the pillow or bed.

In fractures of the patella a circular roller should be carried round it; or it may be done by a compress at the upper part, to prevent the superior portion being drawn up. Mr. Haighton has contrived some straps which answer very well; one applied below and the other above the knee. Having bent it down as low as you think proper, it is to be fastened round the limb, as the former. The limb should be kept straight till the inflammation is abated.

For compound fractures we have the many-tailed bandage; the splints are so constructed as to be easily removed without disturbing the limb. Mr. Sharpe's splints, made of paper and glue, are liable to be softened by the warmth of the limb; also, in compound fractures, where there is much discharge, the matter is apt to rot it. Those contrived by Mr. Martin are better, made like stays, but in some cases they are too pliant; hence wooden splints are the best. These should be defended by padding them well with wool. When the splints are ready the limb may be taken up, and the splints brought under it, so as to adapt them. When the limb is quite at rest we may dress the wound; it is extremely essential, in compound fractures, to keep the limb perfectly still till the callus is formed. The splints should be long enough to contain the whole of the bones, and may be fastened with buckles. The patient lies somewhat easier by having the limb a little raised; lying on one side there is a much broader surface for pressure; besides, lying on the heel for some time produces ulceration there; but there is no rule for laying the limb without exception, as it depends on the situation of the fracture; on this account, in some oblique fractures, we are under the necessity of laying the limb straight, in order to keep the bones more perfectly in their place. When it can be complied with, the bent position, laying the limb on its outer side, is most convenient. This is a considerable improvement in common fractures, which has only been practised these twenty years,

since which we have frequently saved patients with compound fractures in the hospital, which still is not so favourable as in the country, owing to the air and constitution of people in the country being better.

CLINICAL LECTURE

ON

SLOUGHING PHAGEDÆNA—SYPHILITIC ULCERATION OF THE ANUS—SLOUGHING SORES OF THE PENIS, REQUIRING DIVISION OF THE PREPUCE—PRIMARY SYPHILITIC SORES WITH INDURATED BASE.

Delivered at St. Bartholomew's Hospital,

BY WM. LAWRENCE, F.R.S., &c.

Cases of Sloughing Phagedæna.

THE two following cases of sloughing phagedæna, in which the disease had not appeared at the time of admission, but shewed itself some days after the patients had come into the hospital, may perhaps elucidate the origin of the affection, at least negatively.

Margaret Wilson, 25 years of age, had been living in one of the lowest parts of London, as a common prostitute, for twelve months, during which she represented that she had been free from disease. On the 31st May she was admitted, under the care of Dr. Latham, for fever, the symptoms being referable principally to disorder of the head. She was twice cupped on the temple, to six ounces. She took the Hydrarg. c. Creta in the dose of two grains and a half, every six hours, for two days, and, in the two following days, four two-grain doses of calomel; subsequently, saline draughts in the state of effervescence. On June 10th, the feverish disturbance having subsided, she complained of uneasiness in the external organs of generation, which were consequently examined, when a discharge from the vagina was discovered, moderate in amount, without redness or excoriation of the external parts. For this she was ordered to inject a solution of sulphate of zinc. She stated, that on coming to the hospital she was not aware that she laboured under any venereal affection.

12th.—She complained of severe pain in the buttocks, and was examined by Mr. Hott, my house-surgeon, who found in the fissure of the nates, behind the anus, a large deep excavation, with black sloughing surface, from which there was an abundant discharge of thin and extremely fetid ichor. The patient was now removed into a surgical ward, and Mr. Hott made a free application of pure nitric acid to the whole surface of the ulcer, giving afterwards thirty drops of Tinct. Opii to relieve the pain caused by the

action of the escharotic. I saw the patient on the following day, and found a greater loss of substance than could have been expected to occur within so short a time. The chasm measured three inches from before backwards, and two inches in depth at the centre: the entire surface was converted, by the action of the acid, into a dark brownish black eschar; and there was no trace of the fetid ichorous discharge. She had passed a good night, and was no longer in pain: the sloughing process was completely arrested. There was slight discharge from the vagina, without redness or excoriation. The pulse was feeble, and the patient rather pallid and weak; but she had not lost much flesh. The mercurial medicines administered during the febrile attack had not affected the mouth.

Bread poultice. Six ounces of port-wine daily; milk diet with arrow root. A dose of rhubarb and magnesia to open the bowels. One third of a grain of the muriate of morphine at bed-time, if necessary.

14th.—Powdered charcoal added to the poultice.

18th.—Broth diet. 25th.—Meat diet.

A perfectly healthy granulating surface succeeded to the separation of the eschar, and cicatrization proceeded rapidly: the vaginal discharge soon ceased. She left the hospital of her own accord, about the middle of July, in perfect health and strength; but the ulceration had not completely healed.

Mary Ann Lewis, a robust and well-made girl, 18 years of age, was received into St. Bartholomew's on June 18th, 1838. Twelve months previously she contracted a sore on the upper and inner part of the thigh, of which the cicatrix is still evident. It healed in a month without the use of medicine. Three months afterwards she had a glandular swelling in the right groin, which suppurated, and was opened, ulceration of the tonsils, scaly eruption, and pain in the limbs. For these complaints she was admitted into the hospital, and took mercury, which affected her mouth. She soon got well, and was discharged cured in November last. About two months since a bubo came in the left groin; it broke, and the opening subsequently increased and became painful. A week ago she felt a hard swelling at the lower part of the left nympha; it was attended with considerable pain. On the 26th ulceration commenced, with fetid discharge, and spread rapidly. She was admitted on the 28th, when there was a phagedænic ulcer, as large as a crown piece, extending from the left nympha to the lower part of the entrance of the vagina, with copious fetid discharge, inflammatory swelling of the surrounding parts, and great pain:

there was a deep and painful ulcerative excavation, with unhealthy surface, in the left groin. The patient had not lost flesh, and did not suffer constitutionally, except from the pain.

Bread poultice to the ulceration. Pil. Saponis c. Opio. gr. v. every night; half an ounce of the fluid extract of the compound decoction of sarsaparilla, three times a day.

29th.—Black wash to the ulcer at the entrance of the vagina, under the poultice.

On July 28th sloughing phagedæna occurred in the fissure of the buttocks, but proceeded to about one-third less in extent and depth than in the preceding case. The same treatment was adopted, with the effect of immediately arresting the disorganizing process. The sore healed rapidly under simple applications; at the same time the ulcerations of the genitals and groin, treated with black wash and poultice, soon assumed a healthy character, and cicatrized favourably. The patient was discharged on August 6th, without a vestige of local malady, and in excellent health.

The cases now related, with those in a former lecture, illustrate strikingly the destructive nature of sloughing phagedæna. Margaret Wilson is carefully examined on June 10th, when no ulceration exists; and on the evening of the 12th a sloughing chasm, three inches long, is discovered. The progress is equally rapid in Mary Ann Lewis. Perhaps there is hardly any other affection of the ulcerative class, in which destruction so extensive occurs within the same space of time.

It is almost confined to females, who are much more exposed than the other sex to the exciting causes. The case of Reid is a rare example of its occurrence in a male.

It occurs in conjunction with venereal complaints, and on or in the immediate neighbourhood of the genitals; yet it does not seem to be a direct result of infection. It could not, indeed, be produced by the discharge of a similar sore; for the existence of the complaint would absolutely preclude sexual intercourse. Hence the peculiarities of the affection must be derived from circumstances belonging to the individual. It is generally met with in young and delicate females, who lead a life of debauchery in the lowest haunts of the metropolis; injuring their constitutions by drinking, especially spirits, by late hours, and exposure to cold and wet with insufficient clothing. The sexual organs are excited and irritated by excessive indulgence, and do not remain long free from disease. Thus these *unfortunate* females, as they truly call themselves, are exposed to a combination of injurious

influences, general and local, sufficient to explain the occurrence and peculiar nature of this formidable malady. Let me observe, however, that the case of Mary Harmer does not come exactly under this general explanation, according to her own history of the business.

Whatever may be its causes, or mode of production, the malady itself is strictly local. The severe pain causes acceleration of the pulse, impairs the appetite, and prevents rest; effectual destruction of the disorganized surface, by a powerful escharotic, immediately stops the mischief. When the pain of the application has subsided, the circulation is tranquillized, the appetite and rest are restored, and the patient may be considered well. The point of chief importance in managing the sore, is to keep it and the surrounding parts clean; to absorb discharge from the sexual organs, and the secretions of the sore, by lint frequently changed. The part may be covered either by soft lint or by poultice.

Venereal affections are sometimes seen, in which sloughing supervenes on ulceration, but does not spread. The disorganizing process is limited, and the dead part is thrown off naturally. The following is an example:—

Frances Atkins, 20 years of age, had discharge from the vagina, and a small sore on the external surface of the left labium, for which she attended an hospital as out-patient. The discharge ceased under the administration of copaiba mixture. The sore was touched with caustic, and then dressed with black wash; blue pill being given internally. It healed speedily, leaving behind a small hard lump as large as a pea. The induration gradually increased till it acquired the size of half-a-crown. A small spot of ulceration then appeared on the surface, and increased slowly. At the end of a month it assumed a foul aspect, but was not painful. In another week she began to experience pain, but it was not severe. There had been discharge from the neighbourhood of the anus, with severe pain, for two months. She was admitted into the hospital on June 7th, 1838, with an ulcer on the left labium as large as a sixpence, and considerable surrounding induration. There was a black eschar in the centre, surrounded with an unhealthy ulcerated ring. She had also discharge from the vagina, and ulcerated fissures of the anus.

Five grains of blue pill, night and morning;
black wash to the ulcer of the labium and the fissures; bread poultice to the labium.

9th.—The ulcer of the labium is enlarged.

12th.—The eschar has separated, leaving an excavation as if a piece had been scooped out, with a perfectly healthy surface. It

is an inch long, rather less in width, and more than half an inch deep. The sore and the fissures healed rapidly, and the patient was discharged well on the 26th.

This case teaches us, what we have frequent opportunities of observing, that it is not safe, in primary venereal sores with indurated base, to discontinue the mercurial treatment until the induration has been dispersed.

The ulcerated fissures of the anus, which occurred in the case of F. Atkins, deserve your attention, as they are frequently met with, more especially in females, and are often attended with great pain. They are seen under various appearances. The integuments of the anus are sometimes inflamed and excoriated, and ulceration is found in some of the folds. There is a thin and rather offensive discharge, and condylomata sometimes arise in the neighbourhood. The ulcerations may be confined to the skin, or may extend into or be confined to the orifices of the bowel; in the latter case they may escape observation unless the parts are separated carefully. There may be one or more ulcerations at the edge of the anus, with a raised margin of the surrounding integument; the latter being sometimes so prominent as to conceal the sore: this raised edge may be half an inch or more in depth.

These ulcerations, which, from their frequently occurring in the form of chaps or fissures, are called technically *rhagades ani*, have been sometimes considered as primary effects resulting from the direct infection in unnatural practices. They have always appeared to me to be secondary symptoms: they are often accompanied by other forms of constitutional syphilis. I once saw them, in a case which was in all respects singular, as the sole constitutional symptom. Several years ago I received a letter from a medical practitioner to consult me about himself. He had received in the morning a slight wound on the back of the thumb, from a nail, and he was called in the evening to attend a female vagrant taken in labour. Soon after his return home the thumb began to be painful, and the pain increased during the night. In the morning it was swelled and inflamed; and the scratch had ulcerated. He now became alarmed, and immediately proceeded to examine his female patient, whom he found to be affected with syphilis. The ulcer on the thumb spread to the size of half-a-crown. He wrote to me some days after the thing had happened: his account pointed so clearly to syphilitic infection as the source of the mischief, that I recommended to him the use of mercury. At the end of a fortnight or three weeks he came to London; the ulcer of the thumb being then at least as large as a half-crown,

and not disposed to heal; he said that he had suffered much during his journey from an attack of the piles. On examining the anus, I found inflammation of the integument with several ulcerated folds; one of these was one inch and a half long by half an inch deep. The part was excessively painful. He now went through a regular mercurial treatment, under which the primary ulcer and the secondary affection soon assumed a healthy appearance, and in due time healed soundly. This gentleman has never had any other symptom.

Sloughing Sores of the Penis, requiring division of the Prepuce.

James Trench, 37 years old, represented that he had first contracted the venereal disease at the age of 18; and that he had been subsequently affected six or seven different times. He is accustomed to drink freely, and has the pallid unhealthy look indicative of such habits. He observed a small sore behind the glans on April 5, 1838, but neglected it entirely, and continued his usual dissolute habits. He was received into the hospital on the 11th, with the penis swelled nearly to the size of my fore-arm, with the prepuce tense bright red, and drawn over the front of the glans: a thin ichorous and fetid discharge issued in abundance from its orifice. There had been copious bleeding from the same part in the morning and the preceding evening, to the amount, as the patient alleged, of a pint on each occasion. These bleedings, with the fetid ichorous discharge, and the highly inflammatory swelling of the prepuce, shewed that mortification was going on within, and that immediate exposure of the parts was absolutely necessary. I therefore introduced a director between the prepuce and the upper surface of the glans, and divided the former in its whole length to the corona glandis, with a curved bistoury. The divided edges bled freely, the blood running down in a large stream; and thirty ounces were thus lost. The back of the glans and its left side, being at least one-third of the whole, were converted into a dark grey slough; while the corresponding surface of the prepuce was ulcerated with an ash-coloured and sloughy appearance. There was a large ulcer on each leg, producing an abundant and very offensive discharge; the ulcers had not the syphilitic character, nor were they of unhealthy aspect.

The pulse was feeble and frequent; the general strength less reduced than might have been expected from so large a loss of blood within a short time, in a patient with a constitution enfeebled by long indulgence in irregularities of all kinds.

Bread poultice was applied to the penis when the bleeding had ceased; sarsa-

parilla was ordered, and six ounces of port-wine daily. Pil. Sapon. c. Opio, gr. v. every night.

13th.—Pulse quiet, tongue clean and moist; good rest at night. The sloughing extends deeply between the glans and body of the penis: nearly the whole internal surface of the prepuce is in a state of sloughy ulceration. The penis is a little heated, and there has been a slight renewal of hæmorrhage. Powdered charcoal to be added to the poultice, which is to be renewed every six hours. The wine to be discontinued. Milk diet.

18th.—The slough, which never extended after the division of the prepuce, has entirely separated, leaving a healthy granulating surface; the edges of the incision are in the same state. The process of mortification had separated the glans from the corpora cavernosa penis, of which the obtuse anterior extremities were seen at the back of the deep chasm behind the glans. The copious bleeding, previous to the patient's admission, probably proceeded from vessels laid open in this deep extension of the sloughing process. The fibrous covering of the left corpus cavernosum has sloughed to the size of a sixpence, and the dead part is not yet separated. Meat diet, with beer. Although the ulcers of the legs look healthy, and are not painful, the discharge is most offensive, and taints the atmosphere of the ward. Simple dressing, with free use of the chlorate of soda.

On the 25th, it was necessary to administer active aperients, and to return to milk diet. The cicatrization of the sore proceeded slowly but favourably; the glans became again fixed to the body of the penis: the divided edges of the prepuce were drawn up towards the back of the organ, and its figure was thus restored with much less damage than might at first have been expected. Some time was occupied in the treatment of the sore legs; and thus the patient remained in the hospital till June 21st, long after the penis had been completely healed. He went away in much better health than he had enjoyed for a long time previously.

Edward Morris, 21 years old, admitted on June 7th, stated that six days previously he had observed a sore on the prepuce at the root of the glans; that the appearance was trifling, so that he had pursued his usual avocations without employing any treatment. There had been no discharge from the urethra. For the last two or three days the penis had been swelled and painful, and he had been unable to withdraw the foreskin. At the time of admission the prepuce was considerably red, swelled, and painful; there was a copious discharge from

its contracted orifice, of a thin, somewhat fetid, and reddish purulent fluid. The propriety of dividing the prepuce was doubtful, and I decided against the proceeding after considering all the circumstances carefully.

Twelve leeches to the prepuce; bread and water poultice. Frequent injection of tepid water under the prepuce; aperient medicine, followed by salines and antimonials.

9th.—Symptoms nearly the same; continuation of the treatment, with repetition of the leeches.

11th.—The glans protrudes slightly, being partly livid, partly in the state of ash-coloured slough. The prepuce has a lived hue on its upper surface. The discharge is ichorous and fetid. These evidences of serious mischief shewed the necessity of immediately dividing the prepuce, which was done accordingly. Two-thirds of the glans had sloughed, and the whole internal surface of the prepuce was ash-coloured, ragged, and sloughy. Poultice of bread and charcoal.

14th.—The mortified parts of the glans and prepuce have separated; about one-third of the former remains, with rather larger proportion of the latter. The cicatrization was soon completed, and the patient was able to leave the hospital at the end of three weeks.

James Champion, 17 years old, contracted gonorrhœa; soon after which the penis swelled, and became so painful in four or five days, that he came into the hospital on April 9th, 1828. There was great and acutely painful swelling of the penis, with bright redness and tension of the prepuce, phimosis, and copious discharge of bloody fetid fluid. The prepuce was immediately divided in its whole length, along the middle of its superior aspect: it had sloughed on the internal surface to the extent of an inch in diameter, and the rest of the lining membrane was highly inflamed. The glans was inflamed and swollen, bright red, rough, and villous, with numerous small grey specks. There was free bleeding from the cut edges of the prepuce; when it had stopped, a bread and water poultice was applied. Aperient medicines, followed by saline mixture, with antimony. The recovery was rapid in this case: the glans had recovered its natural appearance in 24 hours; nearly all the prepuce sloughed, and the patient went away at the end of three weeks, with no further damage than a permanently denuded glans.

The high inflammation and sloughing which occurred in the three foregoing cases are not referable to the unfavourable character or serious nature of the primary vene-

real affections, on which they supervened; for these affections were slight sores in two instances, and gonorrhœa in the third. These trifling maladies excited inflammation, which was aggravated by imprudent exertion, neglect, and intemperance. The reason why inflammation of the glans and prepuce proceeds so frequently to mortification, must be found in the mutual relations of the two parts exerting on each other a reciprocal pressure, which acts on the glans from without, on the prepuce from within, and becomes more and more injurious in proportion as the inflammation is aggravated. If ulceration of the glans has been the source of the mischief, as in the two first instances, that part suffers, and the gangrene may also extend to the prepuce. If, however, the glans should be sound, as in the third instance, where the inflammation was excited by gonorrhœa, it is probable that the prepuce only will mortify.

The progress of these affections may be arrested in their early stage by an antiphlogistic treatment, particularly free leeching and perfect rest in the recumbent position. But when a state of foul ulceration or of sloughing has come on, the division of the prepuce, as performed in these cases, is the only effectual means of relieving the patient, by cutting short the inflammation, and arresting the progress of disorganization. Copious bleeding takes place from the edges of the divided prepuce; the inflammation is immediately abated, and the patient is soon in a state of ease. The mortified parts quickly separate under simple poulticing, and a healthy granulating surface succeeds in a few days, offering a striking contrast to the destruction met with in first denuding the glans.

It is best, in these cases, to divide the prepuce on its superior aspect, as we want the most complete exposure of the glans. When we are operating for phimosis on parts otherwise healthy, the inferior aspect is the preferable one for the incision.

It is sometimes difficult to decide, whether we should slit up the prepuce, or attempt to reduce the inflammation by other means. Great swelling, with bright redness, tension, and great pain, lead to the suspicion that serious mischief has occurred within. We ought not, however, to proceed to the operation on the evidence of these circumstances only; if there should be, in addition, a dark livid discoloration of the prepuce at some part, we may proceed to use the knife. The character of the discharge issuing from the orifice of the prepuce will assist us in doubtful cases. Should it be puriform and not fetid, the operation need not be resorted to; a stinking ichor clearly indicates that mortification has taken place; and a red offensive discharge, whether thick or thin, leads to

the same conclusion, or to the inference that this change is impending. Whenever, therefore, either of the latter states is seen, in conjunction with the external evidences of high inflammation, the prepuce ought to be divided immediately. In the second of the three foregoing cases, the destruction would have been much less, or, perhaps, would have been altogether averted, if the division had been resorted to when the patient was first admitted. I have seen no instance in which I have judged that the patient would have been better off if the operation had not been performed; but several cases have come under my observation, where extensive and serious destruction had obviously ensued from its postponement.

Cases of Primary Venereal Sores with indurated base (indurated Chancres.)

Charles Springay, 16 years of age, was admitted on April 5th, 1838, with two ulcers on the prepuce, and glandular swelling in the groin, which had existed for one month: no treatment had been adopted. The sores were seated on the base of the prepuce, just where its inner layer is reflected over the end of the penis; one was nearly as large as a shilling, with a more considerably indurated basis. The induration felt like a piece of cartilage under the skin; it was free from pain and redness, and it formed a considerable prominence when the prepuce was drawn back, so as to put its internal layer on the stretch. The ulceration was superficial. In the corresponding situation on the opposite side of the penis there was a superficial sore, as large as a sixpence, without the slightest induration, or thickening at the base. These two sores had appeared at the same time. The glans were enlarged in each groin.

Pil. Hydrarg. gr. v. night and morning; black wash; leeches to the groins.

14th.—The pill to be taken three times a day.

18th.—Being nearly well, he was allowed to go out, and attend as out-patient: at the end of about a week he was perfectly well.

William Andrews, 34 years of age, came into the hospital, May 30th, with venereal complaints, which had begun two months previously, and been allowed to proceed without any regular treatment. He had a large and rather deep ulcer on the left side of the penis, partly occupying the corona glandis, partly the neighbouring portion of the prepuce. The portion of the sore on the prepuce had an indurated base, very similar to that in the preceding case; that in the glans was quite free from inflammation. There was a smaller sore on the prepuce without induration. The tonsils were

superficially ulcerated, and there was a glandular swelling under the jaw. The limbs were painful. Under the blue pill, night and morning, and black wash, the symptoms speedily abated, and he was made an out-patient on June 11th.

Evan Pugh, 60 years of age, was admitted into the hospital, Feb. 22, 1838, with diseased appearances, which were at first puzzling. The integuments of the penis and the prepuce were inflamed and swollen, and the latter could not be drawn back, although its orifice was not much contracted. There was copious puriform discharge. Just within the prepuce, at its lower part, two ulcerated prominences were seen, separated by a fissure. As the prepuce was free above, and no part of the glans could be seen, these prominences, each of which was as large as the end of the thumb, were, at first, supposed to be the glans in a state of ulceration. A more careful examination, however, shewed that this could not be the case; that the glans, probably in a sound state, was behind these parts, and that the prominences were enormous indurations ulcerated on the surface. There was an ulcerated bubo in the left groin. Black wash to the sores; poultice to the prepuce and to the groin. Two grains of calomel, with one-third of a grain of opium, three times a day. This treatment was continued to March 19th, the mouth being considerably affected the whole time: the blue pill, night and morning, was then substituted for the calomel and opium. The mercurial action was attended with a gradual diminution of the indurated swelling, and healing of the ulceration. In proportion as the enlargement subsided, it was discovered that the ulceration had been single, the apparent division having been merely a deep fissure. Pugh left the hospital at the end of March, with the ulceration healed, and the induration dispersed, so that the prepuce could be freely retracted.

Charles Leader, æt. 31, came into the hospital on March 19, 1838. He had phimosis, with ulceration at the orifice of the prepuce. The lining of the latter was generally and considerably indurated, forming a firm mass of cartilaginous hardness, without pain, as large as the last joint of the thumb. The external integument was not involved in the mischief; it could be pinched up and moved over the induration. At the root of the penis there was the cicatrix of an ulcer recently healed. Tepid water to be injected daily under the prepuce, and subsequently black wash; and blue pill three times a day. The ulceration at the orifice of the prepuce had healed, and the induration was considerably lessened at the end of ten days,

when the patient left the hospital by his own desire, to continue under treatment as an out-patient.

The indurated base is a striking concomitant of some primary syphilitic sores, and it attracted the notice of Mr. Hunter. He seems to have investigated the venereal disease, under the influence of a persuasion that the effects of the poison must be peculiar and definite; and he fixed on this as the specific character of chancre. "Venereal ulcers," he says, "commonly have one character, which however is not entirely peculiar to them, for many sores that have no disposition to heal, which is the case with a chancre, have so far the same character. A chancre has commonly a thickened base." Again, in describing the formation of the sore, he says, "a thickening of the part comes on, which at first, and while of the true venereal kind, is very circumscribed, not diffusing itself gradually and imperceptibly into the surrounding parts, but terminating rather abruptly. The base is hard, and the edges a little prominent." Considered generally, this statement is far from being correct: of the various sores produced directly by syphilitic infection the great majority have no indurated base.

The cases of Springay and Andrews exemplify the most common form of the indurated sore in its most frequent situation; that is, in the fold connecting the prepuce to the glans. The hard cartilaginous lump that we meet with in such cases, is generally without redness or pain; sometimes it is red. The ulcer is on the surface of the induration; generally superficial, occasionally a little excavated. Sores at the orifice of the prepuce are sometimes indurated, the hardness being red, consisting partly of a thickening of the skin, less firm and circumscribed than in the other case. The entire orifice is thickened, and indurated in some cases.

The induration may continue, and that for a considerable time after the sore has cicatrized.

Sometimes an induration appears after sores have healed. A gentleman consulted me for two or three small sores, which disappeared in three weeks under the moderate use of mercury. In three weeks more, without any fresh infection, an induration came at the root of the prepuce in the situation of the former sores, and on this a sore formed. When I saw it, (Oct. 28th) the induration was equal to a horse-bean, and the sore to a split-pea. The remedies were blue pill twice daily, and mercurial ointment locally. On November 12th, the sore had healed, but the hardness remained: three pills daily. December 13th, the pills have been continued. Month a little sore; the induration reduced to one-third of its ori-

ginal amount. At Christmas, when the patient left town, the hardness had completely disappeared. This happened many years ago, and the gentleman, whom I am well acquainted with, has never had secondary symptoms.

I have seen induration of the prepuce occur in conjunction with secondary symptoms. A gentleman had primary sores, which were very obstinate. When they had been healed some time, he married. At the end of a twelvemonth there came a large bright red thickening of the prepuce, and a few scaly eruptions on the head. These symptoms were removed by the use of mercury.

The existence, under the surface, of loose cellular tissue, is an anatomical condition necessary to the production of induration. Hence it is frequently seen in ulcers occurring on the lining of the prepuce, more particularly at the angle of reflection, where the part is loose and folded, and the cellular structure abundant and lax; while it is very seldom met with in the glans, where that tissue is in small quantity and compact. The difference in this respect between the prepuce and glans is strikingly marked in sores occupying both parts, as in the case of Andrews, where the preputial portion of the ulcer is indurated, while that on the glans is totally free from hardness. Such instances are frequently seen.

That the occurrence of the indurated base cannot be explained by any peculiarity in the infectious matter, to which the disease owes its origin, may be inferred from such instances as that of Springay, where, of two or more ulcers caused by one and the same infection, one is indurated and the others not.

Although the structure of the glans is unfavourable to the production of induration, this appearance sometimes takes place in a slight degree. I conclude, from the following case, that it may occur as the primary symptom of syphilitic infection. I saw a gentleman on account of indisposition proceeding from cold. He mentioned incidentally that he had observed something unusual on the penis. I found a portion of the glans, towards the corona, rather larger than a sixpence, slightly indurated and elevated, the surface being flat. It was of a brownish red, not ulcerated, excoriated, or painful. This appearance had existed for some days, and might have proceeded from infection, to which he had been exposed. I prescribed a blue pill night and morning, which he took more or less regularly for three or four weeks. I saw him accidentally at the end of six or eight weeks, when he said that the swelling had disappeared.

The indurated base of a syphilitic sore is as much a part of the disease as the ulcera-

tion itself. If hardness should remain after the sore has healed, or if it should supervene on cicatrization, it may lead to a relapse of ulceration, or may be a source of constitutional mischief. The patient, therefore, is never safe in these cases until the hardness is dispersed. This object is easily accomplished by the local and general use of mercury, as the foregoing cases evince. In another patient, who was under my care, in the hospital, the disease, for which no treatment had been adopted, had existed for two months. There was a small and not deep sore of the prepuce, situated on an induration fully equal to the last joint of the forefinger. The enlargement was such that the prepuce, though not otherwise diseased, could not be drawn back without difficulty. Under the use of blue pill, with the local employment, first of the black wash and then of mercurial ointment, the disease was completely removed in little more than three weeks. In the bulk of the induration this case was intermediate between the ordinary smaller examples, and the great mass in the instance of Pugh, which was the largest that I have seen.

OBSERVATIONS

ON THE

VEINS OF THE UTERINE DECIDUA.

By ROBERT LEE, M.D., F.R.S.

HOBOKEN, Rouhault, Ruysch, Albinus, and Ræderer, knew that the amnion and chorion of the human ovum are surrounded by a third membrane, which is in immediate contact with the inner surface of the uterus. The first accurate account, however, of the structure of this membrane of the ovum, and its connexion with the chorion and uterus, was given by Dr. William Hunter, in his *Anatomical Description of the Human Gravid Uterus and its Contents*, in 1794. At page 79, he states "that the decidua is a very soft, tender, pulpy membrane, which lines the whole cavity of the fundus uteri, reaching to the beginning of the cervix and passing a little way within the origin of the fallopian tubes, at which place it is perforated by small openings. It is very irregular in its thickness, some parts being thicker than a crown piece, and others of extreme thinness; but this is subject to a good deal of variety in different persons. In the more advanced periods of utero-gestation, there is not

so much variety in the thickness of the different parts of the decidua, but it is then a thinner and much more uniform membrane."

The inner surface of the decidua, which comes immediately into view when the cavity of the uterus is laid open, is, at an early period of pregnancy, smooth; but the outer surface of the decidua, which is in immediate contact with the uterus, has shooting from it a prodigious number of little processes or flocculi, giving it a very irregular appearance. In the more advanced stages of pregnancy there is little apparent difference to the eye between the outer and the inner surface of the decidua, these flocculi being hardly observable. The adhesion, too, of the decidua to the uterus, at an early period of pregnancy, is not so strong as when pregnancy has made a further progress.

Besides that portion of the decidua lining the cavity of the fundus uteri, which Dr. Hunter used to call, by way of distinction, the decidua vera, another portion forms an external covering to that part of the chorion which is not in contact with the inner surface of the placenta. This was discovered by Dr. Hunter, who called it the decidua reflexa. It is a membrane of considerable thickness, and is sometimes of a yellower colour than the decidua vera. The ovum lies between a part of the decidua vera and the decidua reflexa, both of which unite into one membrane at the edge of the placenta; or the decidua vera divides itself at the edge of the placenta into two laminæ, one of which passes between the placenta and the inner surface of the uterus, and the other forms the decidua reflexa, which covers the outer surface of the chorion."

"Where the decidua reflexa is beginning to pass over the chorion, there is, at an early period of pregnancy, an angle formed between it and the decidua which lines the uterus; and there the decidua is often extremely thin, and perforated with small openings, so as to look like a piece of lace."

I have examined many ova which have been expelled from the uterus in the third month of pregnancy, and in all of them I have observed the openings in the decidua reflexa, thus described by Dr. Hunter, near the angle where it joins the uterine decidua.

These openings are of an oval shape, with smooth margins, and they always pass obliquely through the membrane. If a blow-pipe be inserted into one of these, the interstices of the villi of the chorion and placenta are all readily inflated, and the air soon begins to escape freely from all the other apertures in the decidua reflexa, around that opening into which the blow-pipe had been inserted. If a tube with mercury be introduced into one of these apertures in the decidua reflexa, all the interstices of the villi of the chorion and placenta are likewise readily filled, and the mercury afterwards begins to escape from the numerous openings on the surface of the decidua reflexa. The same thing happens if air or mercury be first made to enter the interstices of the placenta, or villousities of the chorion. These circumstances render it probable that by means of the apertures, in the decidua reflexa, which resemble venous canals, there exists a free communication between the interstices of the chorion, and the cavity formed between the decidua vera and reflexa, and that the maternal blood circulates through these. This is rendered still more probable from the fact, that in the greater number of ova, blood in a coagulated and fluid state is found in the interstices of the villi of the chorion, and that by slight pressure the blood flows readily through the smooth openings in the surface of the decidua reflexa. More or less blood is also found in all cases in the cavity of the deciduous membranes, where these have not been lacerated in the process of expulsion. This fact was pointed out by Breschet and Velpeau many years ago.

The inner surface of that portion of the uterine decidua corresponding with the decidua reflexa is smooth, and is also perforated with a great number of small, oval-shaped apertures. These openings in the uterine decidua are found to communicate with smooth canals, which run obliquely in the membrane towards the uterine surface, and there terminate in larger openings, of an oval form, with thin valvular-like edges. These canals in the uterine decidua have other smaller canals opening into them as they proceed enlarging, towards their termination on the uterine surface. Air or mercury passes readily from the inner to the outer surface,

along these canals, in the uterine decidua.

In many of the ova which I have examined, I have observed the little bags described by Dr. Montgomery, on the outer surface of the decidua vera. On opening these bags, their inner surface is almost always smooth, resembling the inner surface of the uterine decidua, and in several specimens I have observed at the bottom of these sacs, a small smooth aperture communicating with the oblique canals above described in the decidua. Air or mercury introduced into these bags, has passed freely into the canals, and escaped through the openings on the inner surface of the decidua. If a blow-pipe be introduced into one of the apertures on the smooth inner surface of the decidua, the oblique canals in the membrane can all be readily inflated, and the air escapes on the uterine side through the openings in the bags, and through other openings in the membrane. In one instance, what seemed to be a small coagulum of blood filled one of these sacs.

The following is the interesting description which Dr. Montgomery has given of these cup-like elevations in the uterine decidua, and which I am disposed to regard as the terminations of those dilated decidual veins which convey the maternal blood from the cavity formed between the decidua, into the veins of the uterus—

“Repeated examinations have shewn me that there are, on the external surface of the decidua vera, a great number of small cup-like elevations, having the appearance of little bags, the bottoms of which are attached to or imbedded in its substance; they then expand or belly out a little, and again grow smaller towards their outer or uterine end, which, in by far the greater number of them, is an open mouth when separated from the uterus; how it may be while they are adherent, I cannot at present say. Some of them which I have found more deeply imbedded in the decidua, were completely closed sacs. Their form is circular, or very nearly so; they vary in diameter, from a twelfth to a sixth of an inch, and project about the twelfth of an inch from the surface of the decidua. Altogether, they give one the idea of miniature representations of the suckers of the

cuttle-fish. They are not confined to any one part of the surface of the decidua, but I think I have generally found them most numerous and distinct on those parts of it which were not connected with the capillary rudiments of the placenta, and at the period of gestation which precedes the formation of the latter as a distinct organ; they are best seen about the second or third month, and are not to be found at the advanced periods of gestation.”

Dr. Montgomery has added the following note to these observations:—“I confess I am not prepared (nor, indeed, is this the place) to offer any very decided opinion as to the precise nature or use of these decidual cotyledons, for to that name their form, as well as their situation, appears strictly to entitle them; but from having on more than one occasion observed within their cavity a milky or chylous fluid, I am disposed to consider them reservoirs for nutrient fluids separated from the maternal blood, to be thence absorbed for the development of the ovum. This view seems strengthened when we consider that at the early periods of gestation the ovum derives all its support by imbibition, through the connexion existing between the decidua and the villous processes covering the outer surface of the chorion*.”

If the preceding account of the decidual veins be correct, it appears that the circulation in the human ovum in the third month of gestation is carried on in the following manner:—The maternal blood is conveyed by the arteries of the uterine decidua into the interstices of the placenta and villi of the chorion. The blood which has circulated in the placenta is returned into the veins of the uterus by the oblique openings in the decidua covering the placenta. The blood which has circulated between the villousities of the chorion passes through the openings in the decidua reflexa into the cavity between the two deciduous membranes, from whence it is taken up by the numerous apertures and canals above described in the uterine decidua, and so passes into the veins of the uterus.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D'ALEMBERT.

Urinary Diseases and their Treatment.

By ROBERT WILLIS, M.D. Licentiate of the Royal College of Physicians, Physician to the Royal Infirmary for Children, &c. &c.

[Concluded from p. 302.]

RESUMING our account of Dr. Willis's important book, we find the next subject treated of to be *Ischuria renalis*, to which, however, he gives the appropriate name of *Anuria*. The suspension of the urinary secretion for a time, and to a great extent, is occasionally met with in various inflammatory diseases, and after some surgical operations, and the same thing is sometimes met with independently of either such fever or local injury; more especially, it would appear from the experience of Schoenlein and our author, in young children. The same condition is also occasionally seen in the decline of life. The affection comes on insidiously, with constipation, indigestion, and diminished action of the skin, which becomes rough and dry, and is afterwards affected with an itchy papular eruption. The urine becomes diminished in quantity, and progressively more and more high coloured, the voiding it being in some (especially children) attended with much pain. It deposits lithic acid and the lithates copiously. Generally there is accompanying fever, but in the form corresponding to the *ischuria renalis* this is not the case, and Dr. Willis proposes to designate it by the name of *anuria apyretica*. In this the tendency is to coma and death.

“The progress of the disease, and the intensity of the symptoms, vary considerably in different instances. In the generality of cases, coma occurs about the fourth or fifth day from the time when the secretion of urine is totally suspended; and the fatal termination usually happens after the lapse of a few days more. But the secretion of small quantities of urine, which takes place from time to time in some cases, seems to relieve the system in some sort, and then the disease may go on for a much longer period than it ever does when the function of the kidney is

completely annihilated. Under these circumstances anuria may only prove fatal after an interval of several weeks; or, time being allowed for the employment of the proper remedies, it may finally be brought to a favourable issue. There is a remarkable case related by Dr. Laing, of Fochabers, in which not a drop of urine was secreted for between nine or ten days at least, yet in which the patient ultimately recovered completely. Other cases are on record in which the secretion of urine is said to have been suspended for much longer periods. Dr. Parr, in his Dictionary, for instance, mentions one incidentally and without any details, in which no urine was secreted for six weeks. Haller speaks of a patient who made no water for a space of twenty-two weeks; Dr. Berres gives the very interesting details of a child, 12 years of age, in whom there was scarcely a drop of urine voided during more than half a year; but the most wonderful case of all is that which Dr. Richardson has described, in which the patient, if one who was strong and well might be so called, at 17 years of age had never made water in his life! Innumerable other instances might be quoted of a similar kind.”

Some further interesting remarks follow, for which we cannot make room; after which, the author proceeds to express his entire disbelief in the existence of vicarious discharges of urine: he does not believe “that any one organ of the body can discharge the office of any other.” The morbid phenomena discovered on examining the bodies of those who have died have been considerably different in different instances. The most general has been the evidence of inflammation; sometimes the kidneys are harder and drier than natural; sometimes one is enlarged, while in other instances the change has been most apparent in the surrounding adipose and cellular tissues.

As a general rule, the principal remedies are venesection and cupping, followed by a succession of blisters to the lower loins. Dr. Willis expresses considerable confidence in this part of the treatment:—

“As a most powerful auxiliary to these measures, a succession of large blisters, which deserve our best reliance in this disease, and ought never to be omitted, should be applied on either

side of the fleshy mass constituting the sacro-lumbales muscles. It will be better to heal these blistered parts up as quickly as possible, to remove the deadened cuticle by fomentation and gentle rubbing, and then to apply a fresh blister to the place, than to keep the excoriated surface open. The action of the cantharides appears to be positively useful in anuria; and exhibited internally, the Spanish fly has even been recommended as a kind of specific in the disease."

Purgings, antimonials, and diluents, are also recommended; to which may be added stimulating diuretics, as turpentine and cantharides.

The third and five following chapters are devoted to those states in which the urine contains, and usually precipitates, certain foreign matters, forming the variety which we meet with of urinary depositions, including the formation of calculi, under the name of uro-lithiasis. These subjects are extremely well handled, but not of a nature for us to attempt to analyse.

In the second part of the volume we have to do with functional disturbances of the organs which excrete the urine—impediments to its discharge—incontinence—irritability of the bladder—spasm—and, lastly, catarrh of that viscus. Though we cannot enter upon these topics, we may notice *en passant*, that there are—what we should scarcely have expected to meet with in a *medical treatise*—some very judicious observations on the use of the catheter. After describing the treatment to be adopted in ischuria, he proceeds:—

"Should we still be foiled in our attempts by these means to get away the urine by the natural passage, we can then have recourse to the bougie or catheter. It is hardly within my province to speak of this part of the treatment, though I hold that the healing art is one and indivisible; but I may be allowed to recommend, on the strength of my experience in former years, the introduction of a soft plaster bougie of moderate size as a preliminary at all times to the use of any metallic catheter, which is a much less manageable instrument, and, as it is commonly constructed, with large open eyes in the sides near the point, apt to do a great deal of mischief to inflamed and highly irritable surfaces. A bougie having been passed into the bladder and left there for a little time, the urine will

often be found to come away by its sides, and when the instrument is withdrawn to follow it in a rapid succession of large drops, and even in a slender stream. The success in this mode of proceeding is less brilliant, but I believe it to be more certain, and far more advantageous for the patient. The flow of urine once restored, perseverance in the use of the warm or hip bath, of fomentations to the perineum, anodyne clysters, and gentle aperients by the mouth, will soon place the patient beyond danger.

"The introduction of a bougie, however, though it is not followed by the discharge of a drop of urine, is to be viewed as a great point gained; we have an assurance, that the canal of the urethra is pervious, and that instant relief is to be obtained by the brilliant operation of passing a catheter. I shall not dwell on this point, save for a moment to urge on the younger members of the profession, who may do me the honour to glance at these pages, the strong necessity of caution in the practice of this *always delicate*, and with parts affected by disease and changed in their relative position by distension, generally *very difficult operation*. The resources of art are not exhausted even when every effort of the most skilful hand, guided by knowledge, not dominated by force, has failed to carry a catheter into the bladder; an artificial passage for the pent-up fluid can still be made; and though *puncture of the bladder* may, as words, sound more formidably to the ear than the *passage of a catheter*, still I hold the operation of puncturing the bladder to be a trifle, and free from danger in comparison with the evil, and immense risk, encountered under everything like forced catheterism of the urethra. The celebrated P. Desault used to maintain, indeed, that there was no case in which a skilful surgeon could not reach the bladder with a catheter. During the eight years that he had held the rank of head-surgeon at the Hôtel-Dieu, he had only punctured the bladder once, and that was very shortly after entering on the duties of the office."

Here our confined limits oblige us to take leave of Dr. Willis. We have endeavoured only to give such an idea of his work as might induce others to peruse it, feeling assured that they will thank us for having recommended it to them.

Vorlesungen über Materia medica, oder über die Herkunft, die Qualität, die Zusammensetzung und die Wirksamkeit der Arzneistoffe, gehalten 1835—1836 in der Aldersgate's-Schule zu London, von JON. PEREIRA, Esq., Mitglieder der Gesellschaft der Wissenschaften zu London. Deutsch bearbeitet und mit Zusätzen versehen von Dr. FRIEDRICH J. BEHREND, prakt. Ärzte zu Berlin, Mitglieder mehrerer gelehrten Gesellschaften. Erster Theil. Enthaltend die Arzneimittellehre aus dem Thierreiche und Mineralreiche. Leipzig, bei Christian Ernst Kollmann. 1838.

The Elements of Materia Medica; comprehending the Natural History, Preparation, Properties, Composition, Effects, and Uses of Medicines. Part I. containing the General Action and Classification of Medicines, and the Mineral Materia Medica. By JONATHAN PEREIRA, F.R.S. and L.S., Member of the Royal College of Surgeons; Fellow of the Royal Medical and Chirurgical Society; Corresponding Member of the Society of Pharmacy of Paris; and Lecturer in the Medical School of the London Hospital, and at the Aldersgate School of Medicine. London: Longman and Co. 1839.

To the readers of this journal it must be superfluous to say a word in commendation of the articles which stand at the head of this notice. The Lectures of Mr. Pereira have been acknowledged by those acquainted with the subject, to constitute by far the best authority in the English language, in reference to the natural history and chemistry of the articles of the materia medica; while, with respect to their medicinal applications—a department in its very nature admitting of less perfection—he gives in a clear and lucid manner all that has been satisfactorily made out. We regard them as a most valuable portion of our volumes, and we are glad to find them now published separately, in an improved form. As additional proofs of the estimation in which they have been held, we may mention that they are in course of republication, from the pages of this journal, in India; and that there lies before us the first volume of a German edition, published at Leipzig.

MEDICAL GAZETTE.

Saturday, December 1, 1838.

“Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.”

CICERO.

ON MEDICAL STUDIES.

IN the advice which from time to time we have taken the liberty of offering to pupils, we have generally addressed ourselves to that large class who, being stinted in time and money, are necessarily limited to the minimum of study required by the Hall and College. Let us now consider the case of the minority (we hope an increasing one) who intend to go up for examination to the two establishments just mentioned, but, more favoured by fortune, have five or six years for preparation. Instead of spending four or five years in the shop of a general practitioner, and, as too often happens, without learning even the elements of the materia medica, or how to read a prescription, the pupil of the class we are now contemplating, after passing six months in the study of practical pharmacy, will dedicate the rest of his time to professional improvement, unhampered by the useless and deadening drudgery of pounding and mixing. It is hardly necessary to suggest that this emancipation must be the subject of a special agreement, otherwise his master will have a legal claim to his services during the whole period of apprenticeship. Freed from the counter, he is now at liberty to pursue his studies; but as to the best method of laying out his time, he is more in need of counsel than even the pupil whose case we have heretofore considered. The student limited to thirty months must attend the prescribed lectures, and cannot easily attend more; while he to whom time allows an ampler range will not confine himself to the legal minimum; but how

much shall he add, and what subjects shall he select for more careful and reiterated study? Let us endeavour to solve this problem.

In botany, chemistry, and forensic medicine, any addition to the prescribed courses would be unadvisable.

Even the *materia medica*, though far more important than the three subjects we have just mentioned, cannot well obtain more than the hundred lectures ordered in the schedule; for other subjects still more urgent, and far more difficult to master, will demand the student's extra time; and although to him, at the beginning of his career, five years may appear a painfully long period—

“Slow as the year's dull circle seems to run,
When the brisk minor pants for twenty-one,”—

yet, as soon as he is fairly plunged into the ocean that he is to swim through, he will find all the time too short—all his exertions too feeble!

Anatomy can scarcely be studied too diligently. He will enter as a perpetual pupil at some distinguished school, and may begin to dissect as soon as he pleases. According to the regulations of the Worshipful Society, indeed, certain lectures on anatomy, and also a course of demonstrations, must be attended before he dissects; but this regulation need not prevent his dissecting for his own improvement while attending the first course of lectures. How much must he dissect? How long does it take to make an anatomist? Haller says twenty years; the majority of students would move, as an amendment, “three months, and a little grinding.” *Inter utrumque vola*; let the student attend double the prescribed quantum of lectures, and dissect the whole body at least three times; while so doing, he will find it eminently useful to make preparations of all the blood-vessels. It is only the beginner to whom it can be necessary to remark that the arteries

are, as it were, the pole-star of his anatomical studies*, and that in the emergencies of country practice, not to know how to cut down upon an artery is often not to know how to save a life. He will, of course, take advantage of the numerous opportunities of learning morbid anatomy, afforded in every hospital; and if he has profited by the advice of our intelligent correspondent, Mr. Solly, and learned to draw, these opportunities will be infinitely multiplied in value, by the subjects which they will offer to his pencil.

The two courses required on the practice of physie, consisting of one hundred lectures each, appear to us a sufficient quantity even for students of the higher class; but it would be desirable that, during their attendance on these lectures, they should be released from any other pursuit, except hospital or dispensary practice, attending cases at home, and appropriate reading†,—an arrangement which, we suppose, might easily be made, though the strict letter of the law, contemplating a curriculum of only two years and a half, orders it otherwise. Clinical lectures now form a most useful adjunct to the practice of every hospital, and should be most scrupulously followed.

The Society of Apothecaries observe, in their Regulations issued in 1835, that “it appears by the Parliamentary Tables, that *more* than one-half of the

* “I may here repeat that there can be no true presence of mind unless you have studied with care the most essential of all subjects—the surgery of the arteries.”—(Clinical Lecture, by Sir C. Bell, in *Med. Gaz.* vol. i. p. 362.)

† “He used to take notes of the heads of each lecture, and on returning to his lodging, translated into Latin those which had been given in English; he then carefully consulted and compared the opinions both of the ancients and the moderns on the subject of the lecture; to which he added such remarks upon each as his reading and reflection suggested. In his clinical studies he followed a similar plan. When any case occurred to fix his attention, he examined the various authorities which bore upon the point, and formed a comparative result from their evidence and opinions. Many years afterwards he recommended this method to Dr. Lettsom,” &c.—*Family Library: Life of Fothergill*, p. 184.

deaths which annually take place are those of children under five, and of the aged, above seventy, years of age. The diseases of these two classes, and those of women in the pregnant and puerperal state, cannot be studied at hospitals, as they are now constituted.'

In the passage on which this quotation is a note, the Worshipful Society express a wish that the governors of hospitals would re-organize their out-patient establishments, so as to give pupils the opportunity of studying large and important classes of disease, which are seldom seen in the wards. Perhaps they wish for the establishment of a lying-in department of out-patients, which, we believe, is already to be found at several general hospitals; that the really diligent student will find almost every variety of practice among the out-patients whom he visits at their homes. Dispensary practice will lend its aid; and, if we mistake not, there are two dispensaries, or infirmaries, in London, exclusively for children. The maladies which await the other extreme of human existence are perhaps best studied in some great parish infirmary, to which it cannot be very difficult to obtain access.

On surgery it will not be necessary to say much; for to the young and enthusiastic student it is so captivating, that it is rather requisite to check than stimulate his diligence. We do not mean that it is possible to study with too much zest during a given time, but that it is possible for the pupil to forget that he is about to become rather the physician than the surgeon of the community, and to devote to the more brilliant branch of the art of healing that time which should be consecrated to the one which he will be more commonly called upon to exercise. He will probably obtain the place of house-surgeon in one of our

great hospitals, and will there have unlimited opportunities of learning those parts of the art which are the most useful, because the most frequently in requisition.

Dexterity in bandaging, for instance, is often neglected, as if, as Dogberry says of reading and writing, it came by nature; yet how few can put on a bandage tolerably!

To what did Scott, of Bromley, owe his reputation? Bandaging and repose were the whole secret of his cures.

To attend an eye-infirmary is not only advisable, but necessary; and here the pupil will obtain cases to treat himself.

According to the programme issued in 1835, lectures on midwifery and the diseases of women and children were to be attended during the second summer session; while midwifery, with attendance on cases, was among the subjects of study in the third winter session. It appears, however, from a communication with, which we were favoured not long since by our esteemed correspondent, Dr. F. H. Ramsbotham, (p. 160 of the present volume), that an alteration has been lately made in these rules. The law is now, that two courses of midwifery must be attended in separate sessions, subsequently to the termination of the first summer session, which allows the student more latitude. Dr. Ramsbotham recommends him to take advantage of it, by attending the required courses of theoretical instruction during the two last winters, and take cases during the intervening summer. We are not quite sure whether it would be practicable for the 30 months' pupil to add lectures on midwifery to those which he must necessarily attend during the second winter; but the five years' pupil will certainly profit by Dr. Ramsbotham's advice, and spread his obstetrical studies over three sessions *at least*, instead of two. It is superfluous

to recommend him to take, not five or six cases, but fifty or a hundred; for this branch of our art has always led most readily to wealth and fame. Mr. Kinder Wood, a distinguished surgeon-accoucheur, of Manchester, whose biography is to be found in our seventh volume, during his apprenticeship "took rather copious notes of 320 labours, which he had himself attended."

The office of house-surgeon at a lying-in hospital presents advantages which will not be undervalued by those who wish to establish a reputation as well-informed and dexterous accoucheurs.

His studies now gone through, and the five years flown with unexpected swiftness, the student prepares for his examination, and is naturally anxious to know whether he had better have the assistance of a medical tutor; or what, in more familiar phrase, we call a grinder. A ticklish and delicate question! For while, on the one hand, a diligent pupil is unwilling to be confounded with the mob, who know nothing save what the grinder has stuffed into them, and who go up for examination in a state something between an automaton and a parrot; on the other, he clearly sees the advantage of being assisted in selecting from his mass of acquirements those parts which are of most practical utility, and which are, consequently, most likely to be inquired into. Indeed, either the paid help of a grinder, or the unbought advice of a judicious friend, he must have, were it only that he might distinctly know in what points his knowledge is imperfect, or ill-assorted.

However, we will suppose that the examinations are not only safely, but honourably got through. The student, now a lawful practitioner, may direct his attention to those refinements which his pupilage scarcely enabled him to

master, such as auscultation, and diseases of the skin; and if his circumstances permit it, we would strongly recommend an attendance of six months at Paris, were it only to learn medical tolerance, and to become acquainted with the fact, that as "there be livers out of England," so also there be physicians out of Britain.

Another question is likely to spring up, far more difficult and delicate than the one touching the propriety of grinding. It is this: had not so accomplished a student better take to the higher walks of the profession, instead of practising as a surgeon-apothecary? Why, yes—in case he and his friends can give a satisfactory answer to any one of the three following queries:—

Can his family maintain him in comfort and gentlemanly ease for the next ten or twelve years?

Has he such an introduction as is the lot of one man in fifty?

Or, has he such splendid talents as are the portion of one man in a hundred?

If he cannot give the most satisfactory answer possible to one of these questions, we must say "no!" instead of "yes!" If he is to be merely one of the shoal of gentlemanly, half-starved young men, waiting for a chance of practice in the year 1850, who "chat, stroll round the wards, and warm their nether-ends at the board-room fire until two or three o'clock" (*Med.-Chir. Rev.*, April 1837,) we would rouse him from his day-dream of success never to be realized, by most energetic "noes!" We would say to him, beware of these injudicious friends, who mistake fair abilities for unrivalled talents; by all means prefer a certain competence at six or eight-and-twenty, to the chance of clearing enough to pay your house-rent at forty.

DEATHS FROM CARBONIC ACID GAS.

FOUR deaths have lately taken place from carbonic acid gas. One of them has excited considerable interest, as the noxious vapour was produced by a stove which has made some noise in the world, the one invented by Mr. Joyce, and sold by Mr. Harper. It appears from the evidence given before Mr. Payne, the City Coroner, on the 19th and 23d of November, that on the 17th, one of these new stoves was placed in St. Michael's Church, Cornhill, for the purpose of heating it experimentally. James Trickey, the deceased, remained the whole night in the church to watch the effects of the stove, and in the morning was found dead, at the distance of about a yard and a half from it. On post-mortem examination, serum was found in the ventricles of the brain, and much congestion on its surface. Out of five medical practitioners examined on the first day, four were of opinion that Trickey was not killed by carbonic acid gas, but died of serous apoplexy. It is well known, however, that when this gas destroys life, serous effusion into the ventricles is one of the most common phenomena*.

The evidence given on the second day was again conflicting. In the *Times*' report, indeed, Dr. Golding Bird, Mr. Brande, and Mr. Cooper, are all represented to have said that the quantity of carbonic acid gas generated by the stove could not have been sufficient to destroy life; but in the *Times* of Nov. 26th there is a letter from Dr. Golding Bird, giving a very different account of his evidence. He says that on visiting St. Michael's church, after it had been again heated with charcoal in the same stove, "there was lying near the floor, in the middle aisle, a stratum of air sufficiently impregnated with carbonic acid to be, to the best of our belief, exceedingly injurious, and perhaps even fatal, to any one in the recumbent position, and exposed to its influence. . . . And whilst stooping to perform this experiment [testing with lime-water], I unavoidably inhaled this lower stratum of air, and was immediately attacked with severe throbbing of the temples, weight

over the eyes, and a disposition to syncope so great, that I had considerable difficulty in reaching Mr. Blenkarne's house, where some of the air I had collected was examined."

The truth appears to be, that although forty-nine pounds of charcoal could not contaminate the whole air of a church containing about 100,000 cubic feet, they might easily render the air near the stove destructive to life, especially if we suppose the unfortunate deceased to have laid himself upon the ground, or near it. Hence these stoves might be used if we were assured of the consummate prudence of every one who employed them; but not always having this security, we must recommend the public never to heat rooms with charcoal, excepting in a stove with a chimney to it. The verdict of the jury was, "that the deceased, James Trickey, came to his death by apoplexy, accelerated by inhaling impure air."

The second and third case occurred about a fortnight ago, at Greetbam, in the county of Rutland. Two servants, named Temperance Hibbit and Sarah Ann Carpenter, having washed their bed-room, and thinking it not quite aired, took up a chafing-dish full of live coals, which they left burning after going to bed. There was no chimney, and they were suffocated in their sleep by the carbonic acid gas. An inquest was held, and the verdict was "accidental death." The *Rutland Herald* adds with great propriety, "It is a vulgar error that bright or live coals may be used in this manner with impunity, as this melancholy fact most painfully proves." It might also have been observed, that a room without a chimney is of itself an unwholesome bedchamber.

The fourth case occurred last week near London. An inquest was held at the Ordnance Arms, Lewisham road, on the 27th of November,† on the body of George Bell, who was discovered in a burning lime-kiln on the 22nd. He was not burnt, but in a state of stupor, with low pulse, convulsions, and aphonia. He survived till the 25th*. There appears to have been no dissection, and we are left to conjecture that Bell died by some form of apoplexy. We wish that in this case, but more particularly in Trickey's, the medical

* Beck's Medical Jurisprudence, 5th edit. p. 551.

† *Times*, Nov. 28th, 1838.

evidence was published by the practitioners who gave it, as it is not very easy to collect from the reports, what they really said.

THE LATE M. BROUSSAIS.

THE death of this distinguished physician, which we announced last week, took place at his country house at Vitry. His immediate decease was rather sudden, but he had long laboured under cancer of the rectum.

Broussais was born at St. Malo, in December, 1772, and was therefore sixty-six years of age when he died. In 1792 he entered the army as a private soldier, but soon afterwards became an *officier de santé*. He subsequently served in a trading vessel during a period of six years, after which he went to Paris, and graduated as Doctor in Medicine. His thesis was on Hectic Fever, and was dedicated to Pinel.

Subsequently to this he followed the campaigns in Holland, Germany, and Spain; and it is said to have been amid the fatigues of military service that he conceived the plan of the work to which he owes his celebrity—the History of Chronic Phlegmasiæ. Of this the fifth edition was published in Paris during the current year.

Broussais was Physician-in-chief to the Val-de-Grace; Professor of General Pathology in the Ecole-de-Médecine; and a Commander of the Legion of Honour. His appointments brought him 10,000 fr. per annum.

He was attended in his last illness by M. Amussat, and when arrested by death was actively engaged in a reply to the Memoir of M. Jouffroy against Phrenology, and in preparing a new edition of his work on Irritation and Insanity. There was a rumour, arising probably from the abruptness of his death, that he had been poisoned; but there seems to have been no ground for such a suspicion, and it appears to have speedily subsided.

M. Broussais was buried on the 21st of November, on which occasion all the usual display and parade which mark such scenes in Paris were exhibited. A crowd of practitioners and pupils were assembled in the Rue d'Enfer; military medical officers, and the members of the Ecole, in their official dresses; deputations from the Academy of Sciences and

of Medicine were in attendance, to say nothing of a detachment of troops. This imposing *cortège* proceeded to the Val-de-Grace, MM. Larrey, Orfila, Boissy d'Anglas, and Droz, being the pall-bearers. Divine service having been performed in the chapel, the procession proceeded, the students having taken out the horses, and dragging the hearse all the way to Père-la-Chaise.

Discourses were pronounced over the grave by MM. Droz and Arago, in the name of the Institute; M. Larrey (*fls*), on the part of the military medical officers; and M. Bouillaud, on that of the Ecole de Médecine.

The officers at the Val-de-Grace propose to go into mourning for a month, as a testimony of their affectionate respect for the deceased.

WESTMINSTER HOSPITAL.

CLINICAL LECTURE BY JNO. BURNE, M.D.

October 29th, 1838.

Nephritis, Anasarca, Albuminous Urine, Pneumonia.—Chronic Renal Anasarca, Albuminous Urine, Bitartrate of Potass.—Ascites, Anasarca, removed by Bitartrate of Potass.

GENTLEMEN,—Associated with the case of nephritis and anasarca, which formed the subject of last week's lecture, is that of Isaac Bailey, also labouring under nephritis and anasarca, but complicated with pneumonia.

CASE XVII.—*Nephritis, Anasarca, Albuminous Urine, Subacute Pneumonia.*

Isaac Bailey, aged 42, a labourer, whose health was generally good, with the exception of having been liable to a cough on taking cold, for the last five or six years.

About the 22nd of September, 1838, he got wet in the feet from washing casks, after which he had a diarrhoea, and then tightness across the chest, short breath on exertion, and cough. On the ninth day after having got wet, the scrotum swelled, and the face and hands began to be œdematous.

On the 12th of October he was admitted into the hospital, affected with œdema of the scrotum, penis, face, and lower extremities; of the trunk, also, in some degree, and complained of fulness of the epigastrium and abdomen. The appetite was good, but he felt full and bloated after eating; the urine brown red, dingy, highly albuminous.

Capiat Elaterii, gr. ʒ, mane quotidie.

Oct 15th.—The urine less brown; the oppression at the chest continues, and the cough is troublesome.

Sanguis à brachio ad ℥viij. detrahatur. Perstet.

18th.—The blood not buffed; the serum pale; the chest relieved by the loss of blood. He felt "lighter," and hungry immediately afterwards. The anasarca swellings begin to diminish; full diet, at his own request.

21st.—The elaterium, which has been persevered in, purges him twelve or fourteen times a day, and at first vomited him also. The dejections are watery and copious; the anasarca not further diminished since last report; but the urine has lost the red brown colour, and is now of dingy straw colour, opalescent, acid, and equally albuminous. He complains of renewed tightness across the chest; dyspnoea, so as to prevent him lying down, and of a troublesome harsh jarring cough, which is worse at night.

Auscultation.—Left lung; crepitating wheeze posteriorly and inferiorly. Right lung; respiration bronchial, with dry valvular, and rather hissing wheeze here and there on expiration.

Diagnosis.—Inflammation of inferior lobe of left lung, and bronchial congestion of the right lung.

Omittatur Elaterium. Sanguis ad ℥viij. mittatur.

R. Antim. Potassio Tart. gr. ½; Hydrarg. Chloridi gr. j. M. 4ta quaque horâ.

22nd.—Immediate relief followed the blood-letting; the respiration has become freer, the cough is less jarring, and he is able to lie down. No buff on the blood; the serum pale, and rather abundant.

Perstet.

23d.—The mouth become sore already from the calomel.

Hydrargyrum omittatur. Antimonium repetatur, 6ta quaquâ horâ.

28th.—The soreness of the mouth increased to profuse salivation, notwithstanding only ten grains of calomel have been taken. The cough is very much better, and the breathing nearly as well as usual. The crepitation is no longer heard, but is replaced by bronchial respiration; the wheeze of the right lung has subsided, and respiration is less bronchial and more vesicular. The dropsical swellings have diminished gradually for the last seven days. The antimony was omitted on the 25th; and the discharge from the mouth being very great, no other medicine was prescribed than

Sulphuris gr. v. bis quotidie. Pulv. Jalapæ Comp. ʒss. prout res postulat.

In this case of Isaac Bailey there was the same pathological condition of the kidneys as existed in Richard Wood, and the same dropsical infiltration; but in Bailey the renal disease became complicated with a pneumonia, which adds to the difficulty of cure.

The anasarca supervened on the ninth day after the accidental cause, but he did not come under treatment till the twentieth day, when the dropsy had consequently existed eleven days.

It is remarkable how little pain attends these cases of nephritis in general; so that on inquiring of the patient the history and early or present symptoms of his case, the chance is that he will not allude to the back or kidneys, unless his attention is called to the subject, and then he remembers to have felt more or less pain in the loins quickly after the exposure, but which pain was never regarded by him as a feature of his complaint. Neither is there irritation of the urinary organs; nor does he of himself offer any remark relative to the altered quantity or condition of the urine. It is not, therefore, until the dropsy has actually appeared, that any renal affection is suspected. The urine is then examined, found to be albuminous, and the kidneys thus discovered to be diseased; so that not only days, but, as in the case (XVI.) of Richard Wood, even weeks may elapse before the organic affection comes under treatment; all which time the structure of the kidneys is being impaired; and the impairment may have proceeded to an extent absolutely irremediable, before any efforts are employed for its arrest or relief.

If, then, in the early stage, before dropsy has supervened, there are no local signs by which to determine the presence of a nephritis, on what can we rely? On the urine only. If a healthy person, having taken cold, is seized with rigors, followed by febrile movement, and if his urine gives evidence of the presence of albumen or of blood, you may regard this sign as pathognomonic of inflammation of the substance of the kidneys, and have recourse to antiphlogistic measures accordingly. Could the renal inflammation be discovered thus early, and treated with decision, there is every reason to hope that it might be arrested and subdued, and the structure of the kidneys saved from disorganization; but if the disease has not been suspected till the dropsy has supervened, much time and fair opportunity may have been lost; for experience leads me to the sad conclusion, that if the renal affection, as indicated by the albuminous urine, has existed one month from its first invasion, the granular disorganization will have already advanced to a degree incu-

nable; and that although by treatment the dropsy may be removed, the disease will not be eradicated, the urine will still remain albuminous, the dropsy will assuredly return, and lead, within six or twelve months probably, to a fatal termination.

The treatment must depend entirely on the stage of the disease.

Regarding the disease at the outset as a pathological congestion or inflammation, this state of inflammation may be considered the *first* stage. The inflammation still continuing, but now subacute-chronic, and morbid deposit taking place in the proper tissue of the kidneys, may be considered the *second* stage; and at a later period, the kidneys having become loaded with the morbid deposit, and beginning to be indurated, the inflammation having subsided altogether, may be considered the *third* stage. The *fourth* and last stage is that in which induration, accompanied with atrophy, has advanced to the greatest degree, the kidneys having acquired a gristly hardness, and having wasted to half their normal size. This morbid change in the structure of the kidneys assumes a *granular* form, and is hence called the granular disease of the kidneys. The morbid deposit, the product of the inflammation, is not organizable; and therefore, although in the first stage you have the kidneys in the state of the intense vascularity of inflammation, yet this diminishes as the morbid deposit takes place, so that in the third stage the kidneys are less vascular than natural; their proper tissue consequently pale instead of red-brown; and injections no longer penetrate, as in the healthy organ. In these drawings the appearances of the kidneys in the various stages are well delineated.

It is clear, then, that antiphlogistic measures can only be employed with vigour and with success in the first stage; but, inasmuch as the dropsy supervenes at such various and uncertain periods from the nephritic attack, the dropsy is an uncertain criterion of the stages. The best evidence to guide you is the time that has elapsed since the seizure; and in proportion as this is short, so may you have recourse to the abstraction of blood; in proportion as it is long, so must blood be drawn less freely. In the cases of Wood and Bailey, for example, the blood-letting was to the extent of only ten or eight ounces, once in the former patient, twice in the latter; and the watery appearance of the serum, especially at the second bleeding of Bailey, and the progress of the cases since the blood-letting, afford no cause of regret that more blood was not drawn; on the contrary, harm would, I

think, have resulted had blood-letting been persevered in. If these cases had come under my care within a week after the invasion of the nephritis, as indicated by the accidental exciting cause and the albuminous urine, I should have bled the patients largely and repeatedly, in the hope of averting that termination which I fear both are destined to experience. In addition to blood-letting, hot baths at this period may be a valuable auxiliary in the treatment.

Mercury is a remedy of doubtful efficacy, though so valuable in other organic inflammations. I have observed that these patients become salivated very speedily; that the salivation is often profuse and of long continuance, and the benefit in no way proportionate; yet I should be sorry to discard mercury as a therapeutic agent in renal disease, until I had employed it repeatedly in the inflammatory stage, which yet I have had no opportunity of doing.

Beyond these remedies, elaterium, where the dropsy has supervened, is valuable, not only as a means of removing the aqueous infiltration, but of determining from the kidneys. Iodine, also, in its various forms, and counter-irritation, deserve a trial in our endeavours to remove the granular deposit, and so to restore the kidneys to their normal structure and function.

The dropsy which results from disease of the kidneys is not merely anasarca—that is, according to Cullen, “a soft inelastic swelling of a part or of the whole body.” It is not limited to the integuments of the body, but may be, and often is, infiltrated into every tissue, and effused into every cavity: it is a universal dropsy, and its character consequently is ill represented by the term “anasarca.” I therefore propose the word *cathohydrops*, compounded of the Greek *καθολικός*, *generalis*, *universus*, and *ὑδρῶψ*, *hydrops*; not, however, with any vain desire of introducing a new name, but really with a view to furnish one which shall represent truly this condition of universal dropsy.

The subacute pneumonia which supervened a few days after Bailey was admitted into the hospital yielded readily to the loss of blood, aided by the calomel and antimony. It is not uncommon in these cases of renal dropsy for an intense organic inflammation to attack the patient most suddenly, and to prove fatal in a very few days. I have seen this occur, without being able to trace it to any exciting cause.

The next case which I shall present to you is also one of renal anasarca, not recent, but of long standing, in which the

efficacy of the bitartrate of potass, in removing the dropsical infiltration, is remarkable.

CASE XVIII.—*Chronic Renal Anasarca removed by Bitartrate of Potash.*

Thomas Oliver, aged 29, a milkman, an out-patient.

History.—In the spring of 1837, he caught cold, and was seized with severe pain across the kidneys, violent cough, general indisposition, and swellings of the legs. The cough continued for three months, and then left him: the swellings were removed entirely by a slight salivation, and he considered himself well.

In the autumn of the same year the pain in the back and swelling returned, in consequence of a cold; the swelling hitherto having been limited to the ankles.

1838.—He applied as an out-patient at the hospital on the 4th of January last, at which time he had anasarcaous swelling of the lower extremities and scrotum; but his bodily health was, according to his own report, as good as ever; the appetite being good, and he without complaint, except the dropsical swelling.

He was of middle stature, 29 years of age, rather thin and sallow: he had formerly been a sailor on the Mediterranean station, but had not suffered from serious illness at any period of his life.

The urine was pretty clear, of a greenish tinge, highly acid, and albuminous.

He took various medicines of a purgative and diuretic kind for nearly a month without relief; when the bitartrate of potass, in the dose of \mathfrak{ss} . three times a day, was prescribed. This had an immediate effect on the kidneys, and the dropsical swellings of the lower extremities and scrotum disappeared in three days, much to my surprise. He continued the medicine for some time, and was discharged at his own request, believing himself cured.

At the latter end of March the anasarca returned; he resumed the bitartrate, which dissipated it as rapidly as before. He said he could observe a diminution of the swelling after a single dose.

Again, in June, the dropsy returned, and again was removed by the same means.

He is now, October, under treatment a fourth time, and as before, receiving benefit from the same remedy, but the urine continues to be albuminous—a character which it has never lost since he came under my care.

When Oliver first applied for relief as an out-patient I had no opportunity of testing his urine; and from his sallow

complexion, I thought the dropsy might be connected with lesion of the liver, perhaps of the heart, both which organs I examined without finding any evidence of disease. I desired him to bring some urine on the next day of attendance; which urine, being tested, gave unequivocal signs of albumen; and thus cleared up all doubt as to the nature of the case. It may be concluded that he is affected with granular disease of the kidneys, arrived at the third stage.

The relief which he experiences, however complete as respects the dropsy, will be only temporary, the removal of the cause being beyond the reach of medicine.

In another case which you have recently witnessed, the bitartrate of potass was equally efficacious, in dissipating not only an anasarca but an ascites; the dropsy not being renal, but proceeding from disease of the heart, and perhaps also of the liver.

CASE XIX.—*Ascites—Anasarca removed by Bitartrate of Potass.*

Mary Ewart, aged 42, admitted on the 17th of June, 1838; a married woman who had borne nine children, the youngest being 13 months old; she was emaciated, and had the linear aspect of visceral disease.

She laboured under ascites, also anasarca of the lower extremities and pudenda, and shortness of breath; and her appetite and general health were bad. The action of the heart was strong, irregular, and intermitting; while the pulse was small and weak. The urine was high-coloured, clear, scanty, free from albumen.

During the first fortnight she took several diuretic and purgative medicines, without effect upon the dropsy, and without benefit to her health. I then prescribed

\mathfrak{R} Potassæ Bitartratis, \mathfrak{zss} .; Sp. Æther. Nitrici, $\mathfrak{f. \mathfrak{zss}}$.; Tinct. Scilla, $\mathfrak{f. 3ii}$.; Mist. Camphoræ, $\mathfrak{f. 3vii}$. M. $\mathfrak{3j}$. ter quotidie.

The effect of which was to produce an almost immediate increase in the urine, and improvement in the appetite and general health. The anasarcaous swellings of the extremities and pudenda passed away, and the ascites gradually diminished, so that on the 17th of July she was free from all signs of dropsy, and in comparatively good health; the state of the heart and circulation remaining unaltered, though the respiration was no longer embarrassed. She continued the medicine for some time after her discharge from the hospital; but having left it off, the urine began to diminish soon afterwards, and the dropsy threatened to return. She had again re-

course to the bitartrate, which promoted the urine as before, kept her free from dropsy, and in good bodily health when I last saw her, on the 10th of September.

The dropsy was here dependent mainly on the disease of the heart and arteries: though, from her appearance, it is probable that the liver was in some degree indurated, and might have aided in producing the ascites. Be that as it may, the ascites and the anasarca both disappeared under the use of the bitartrate of potass. As in the former case, so here the relief is only temporary; the dropsy, though removed, will return, the cause persisting. In all cases of this description, where the organic mischief is irreparable, we can only direct our measures to the removal and the prevention of consequences.

There is no class of remedies so capricious in their operation as diuretics. On one occasion, the diuretic will succeed; and when next tried, under similar circumstances, will fail altogether. When the object in the treatment is to promote the secretion of urine, all the diuretics should be tried in succession, not disregarding the most simple and vulgar; for I have seen all combinations tried in vain, and *leek* tea, taken at the suggestion of an old woman, cause the kidneys to secrete gallons in the twenty-four hours, and dissipate an anasarca. Unquestionably the favourite combination of squill, digitalis, and blue pill, is on the whole the most certain and efficacious, but it fails constantly; and then we must use in succession all which the materia medica and the herbalist supply.

The late Sir William Knighton told me one day, when we were conversing on medical subjects, that he had often found digitalis act, if ammonia was given in conjunction, but inert when given alone. Remembering this hint, I have latterly combined the ammonia with other vegetable diuretics; the influence of which it has materially aided. At this time I have a gentleman under my care with ascites, who had taken various diuretics without promoting the action of the kidneys: at length the seoparium was tried, also without effect, till six or seven grains of the sesquicarbonate of ammonia were added to each dose. The secretion of urine then increased considerably, and the size of the abdomen diminished three inches in the course of a week.

WESTMINSTER MEDICAL SOCIETY.

November 17, 1833.

DR. CHOWNE, PRESIDENT, IN THE CHAIR.

Dropsy of the Womb.—Vulgar prejudice in favour of Bleeding in cases of Sudden Accident.—Vaginal Hernia.

DR. REID related the case of a woman about 26 years old, who had arrived at the full period of utero-gestation in good health, till the last three days, when she entertained a presentiment that she should not survive her accouchment, and she made preparations for her death. On the 6th day of November instant labour-pains came on, and remained some hours without producing any effect on the os tincæ. The midwife in charge at length gave thirty drops of landanum, and thus succeeded in arresting the pains. On the 7th, the bowels being bound, an ounce dose of castor oil was given, and repeated every four hours for several times without any effect.

On the 8th the patient was taken into St. Giles's Infirmary, at 3 P.M., but the labour-pains had not recurred. Complaining of not having made water, the catheter was introduced, and about two ounces only of urine were withdrawn. Warm laxative injections were thrown up the rectum without benefit. During the night of the 9th she had slight pains in the loins, but the bowels were still unmoved. Dr. Reid saw the woman for the first time on the 10th, at 11 A.M., and found her feverish. She had pain on pressing the upper part of the abdomen. The belly was very prominent, and the infant could be distinctly perceived through the walls. The foetal pulse was ascertained by the stethoscope to be 140. Examination per vaginam exhibited the os uteri dilated to the diameter of an inch; the membranes were tense, and the child's head receded when touched by the finger. The lips of the os tincæ were thick, but healthy. He inferred that there existed a large quantity of the liquor amnii, and perhaps twins.

Dr. Reid ordered a clyster with castor oil to be injected without delay, and an aperient dose to be given every four hours. No result, however, was produced; labour-pains came on sharply in the afternoon; and between six and seven o'clock in the evening the os uteri was well dilated. The pains became more and more energetic, and an average-sized living child was expelled. The membranes did not break until the occurrence of the last pain, when two gallons of the liquor

amni escaped from the womb. It was caught in a pail and measured. There was no hæmorrhage. The placenta came away in twenty minutes, and the womb contracted regularly, but the upper region of the abdomen remained large, and there was fluctuation perceptible. The patient was for two hours very comfortable, but after this lapse of time she became restless. The resident surgeon finding her low, gave her hot brandy and water; and hot flannels were wrapt round the feet.

At 11 P.M., Dr. Reid found the patient pulseless, and her extremities cold; she was restless, throwing her limbs about incessantly. She refused all stimulants, and would take nothing but cold water; after this she vomited frequently, her breathing became heavy, but she complained of no pain whatsoever. Dr. Reid found the uterus well contracted. There was no hæmorrhage, nor further discharge of fluid. She died at one o'clock in the morning. Her friends removed her body to her own habitation, and a large quantity of water escaped into the shell where she lay. When the undertaker moved her into her coffin, he was obliged to bore holes into the bottom, that the fluid might run off. At this period, large quantities of excrement passed from her, and she became so offensive that her friends buried her the day after her demise.

No autopsy being permitted, Dr. Reid felt doubtful as to the cause of death. After the discharge of the liquor amni, the patient did not complain of faintness, or any other unpleasant symptom. After the uterus was well contracted, there was a great discharge of water from that viscus. Could this have been a case of uterine dropsy, complicated with ovarian dropsy or ascites? and could the fluid from the abdomen or ovary escape by the fallopian tubes into the uterus? Instances of this description were on record, but Dr. Reid had not read of any cases exactly similar to the one just sketched. Dr. Ramsbotham had recorded a case of ascites during pregnancy, where tapping had been resorted to, in consequence of urgent symptoms previous to parturition. The obstinate constipation in this case he thought was dependent upon the lateral pressure of the fluid upon the bowels.

This history provoking no discussion, Mr. Smith reported a case of ulceration of the ileum, which was concomitant with the subsistence in that bowel of a large *lumbricus teres*. This parasite was discharged a short time before the death of the patient from peritonitis.

Mr. Pettigrew had seen several cases in which the *lumbricus teres* was the cause of ulceration of the mucous membrane.

Dr. Johnson thought Mr. Pettigrew rather peremptory in his opinion; his own experience did not lead him to the same conclusion, for he considered the ulceration would act as a cause for the expulsion of the worm, whose food was the natural secretion of the mucous lining, not the purulent secretion of an ulcer. The existence of the peritonitis was quite sufficient cause to produce the dislodgement of this class of parasites, by the increased peristaltic action which it excited.

Mr. Bushel related a case in which he had known the side of the bowel penetrated by a *lumbricus teres*. There was simply a perforation, without any ulceration.

A slight discussion occurring touching the value of the *hymen* as a sign of virginity, Mr. Streeter gave the history of a case in which the hymen obstructed the delivery of a respectable married woman, at her full period of gestation. Mr. Streeter was at first a little puzzled, but having by examination satisfied himself that it was the hymen, very tough, and with an aperture in its centre large enough to receive the tip of the index finger, he divided the obstructing membrane with a pair of scissors, and the child, breech foremost, was easily protruded.

Mr. Davey, a respectable practitioner residing in the neighbourhood of Manchester Square, applied for advice to the Society as to his future conduct in an unpleasant emergency in which he had become implicated. Some days since he had been called to a stranger, who had become suddenly affected with asthmatic dyspnoea. He had given him an antispasmodic remedy, and the patient perfectly recovered apparently, and returned to his home in a distant part of the town. Soon after his return he died, and two medical men being called in, declared it as their opinion that the man died because he had not been bled. Mr. Davey was of opinion that the patient was not in a condition to stand bleeding, for he was aged, and suffered from what he considered to be asthma, complicated probably with some disease of the heart or great blood-vessels. The pulse was powerless. The opinion of these medical men had travelled to Mr. Davey's neighbourhood, and there spread like wildfire, injuring him very much in the opinion of his neighbours. Mr. Davey insisted upon having a coroner's inquest upon the body. The court assembled, and refused admittance to a medical friend of Mr. Davey's, who was desirous of affording the jury some explanation of the circumstances of the case. They gave a verdict of "died

by the visitation of God," and the prejudice against Mr. Davey, in his own neighbourhood, remained as strong as ever.

Some observations on this case followed; but Dr. Chowne, the President, now interfered, observing that the subject under discussion was of a medico-political character, and therefore forbidden by the laws of the Society.

Dr. Johnson narrated the history of a case to which he had been called two or three days previously at Pentonville. The patient, a woman, had for some days been confined to her bed, with severe pains in the loins. The day before he saw her, she had walked out. At the first interview she was in great distress, and told the doctor that "her womb was in the world." On examination, he discovered a tumor, like the head of a child, protruding from the vulva. It was soft and elastic, and the Doctor was at first induced to think it was the bladder. It gave way upon gentle pressure, and then he was enabled to detect the uterus and bladder *in situ*. The tumor, in his opinion, was a hernia of the rectum pressing forward the posterior wall of the vagina through the vulva. On withdrawing the hand, the swelling again protruded. He placed the patient in a recumbent posture, and introduced a large sponge into the vagina. This was to be followed by the use of an astringent wash. He (Dr. Johnson) would be glad to know if the learned president, Dr. Chowne, had met with a similar case in his extensive experience.

Dr. Chowne said that if he had been called in to such a case, or had heard it described in the same terms as Dr. Johnson had used, without the opinion which Dr. J. had given, he should unhesitatingly have pronounced the case to be one of vaginal hernia, in which the small intestines passing down between the uterus and rectum, carried forward the back wall of the vagina, and formed a hernial pouch at the opening of the vulva. He had seen many such cases, but he had never seen one of prolapsus of the rectum, which was an affection of extreme rarity. However, he had so much respect for Dr. Johnson's diagnostic powers, that he should be sorry to put his own opinion against his.

A member inquired of Dr. Johnson whether he had passed his finger into the rectum of the patient during the protrusion, as that would have been an *experimentum crucis*, and would have left no doubt upon the point.

Dr. Johnson said he had not done so when the rectum was dislocated, and he did not think it prudent to let it prolapse

again for the sole purpose of passing his finger into the rectum. Sir Astley Cooper had published a case similar to the one he had just described.

Mr. Snow had once seen a case, which had occurred during labour, of prolapsus of the walls of the vagina all round, presenting at the vulva like the head of a fetus. He reduced the parts by gradual pressure. The hour (10 P.M.) having arrived, the President struck the table with his mallet, and the meeting broke up.

18108.

TREATMENT OF BURNS.

To the Editor of the Medical Gazette.

SIR,

IN Mr. Meade's interesting paper on the treatment of burns and scalds, I find he cannot see the analogy between Dr. Greenhow's practice and my own. If he will take the trouble to repereuse my paper, he will find me to state in the fourth line—"and was forcibly struck with the coincidence of his practice (Dr. Greenhow's) and my own for several years past, varying only in the nature of the composition used." By this statement the tenets which Mr. Meade has advanced, shewing treacle to differ in its action from Dr. Greenhow's stimulating composition, is admitted; and again, at page 192, column 2, he will find, "where vesication is large and extensive, I prefer a thick coating of treacle upon the part, and afterwards envelop it with cat paper" (vulgarly so called; tissue is a better substitute. If suppuration does not occur, I wash the treacle off in five or six days, and generally find the part well.) A thick coating of treacle, in my humble opinion, is analogous to a thick coating of the stimulating composition used by Dr. Greenhow, and answers the same useful purpose of preventing contact of the burnt surface and atmospheric air. I have tried it in this manner in deep burns, but cannot recommend its use in these cases.

If Mr. Meade will give the treacle dressings a fair trial, and use them only in the cases I have spoken of, he will not only be an advocate of their virtues, but extol them as a boon to the philanthropic inquirer.—I am, sir,

Your obedient servant,

JESSE LEACH.

BLOWING HOT AND COLD ON DR. JACOB.

(From a Correspondent.)

LANCET of 17th November, 1838.

NOTE to page 306 (referring to Dr. Jacob's lecture in Dublin).—"On looking over this *precious* document, we find that it is a *radical* Address by Professor Arthur, which had found its way, by mistake, we suppose, into the *Protestant* Guardian—*Fas est et ab hoste*.—ED. L."

LANCET of November 24, 1838.

Page 351.—"The substance of an Address* which has just been delivered in the same place by Professor Jacob, is not less worthy of the notice of the friends of an *improved* system of government in medicine. We shall with much *satisfaction* find a place for it in the next Lancet."

How is this change of tone in the two editorial articles on the *same* Address, within the space of eight days, to be accounted for?

DEATH FROM SUFFOCATION MIS- TAKEN FOR APOPLEXY.

AN inquest was recently held at the Marlborough Head, Shadwell, on the body of a man, named Sullivan, a cabman, aged 45. It appeared that on the preceding evening, while partaking of a repast at an eating-house in the Back Road, he was suddenly seized with a sort of fit or spasm, and left the room. On getting outside of the door he became sick, and in a few minutes dropped down in a state of insensibility. He died immediately afterwards. The medical gentleman, to whose residence he had been conveyed, gave it as his opinion that he had died of apoplexy. The coroner, however, here remarked, that in the course of his official experience, two or three cases of a similar nature to the present had come before him, in which he felt it to be his duty to direct the professional witness to open the gullet of the person deceased, and, on this being done, it was satisfactorily proved, by the fact of large morsels of meat being closely fixed therein, that the parties had died of suffocation; and he should not be surprised if such should turn out to be the fact in the instance before them. The medical witness then, at the request of the coroner and jury, proceeded to the place where the body was deposited, and in a short time returned with two large gristly pieces of boiled beef, weighing about three ounces, which he found blocking up the

œsophagus, and which he thought sufficient to have caused the death of the deceased by suffocation. A verdict to that effect was returned accordingly.

BOOKS RECEIVED FOR REVIEW.

The Chirurgico-Comico Alphabet. By Pill-Box. [The author of this attempt at humour has most lamentably mistaken his *forte*]

The Medical Annual, or British Medical Almanack for 1839. Edited by William Farr. [Useful, and well worth purchasing, but having the same imperfection as in former years.]

AN
INTRODUCTORY DISCOURSE
ON THE
STUDIES REQUIRED FOR THE
MEDICAL PROFESSION.

ADDRESSED TO THE STUDENTS OF THE
MEDICAL SCHOOL OF ST. GEORGE'S
HOSPITAL,

October, 1, 1838.

By SIR B. C. BRODIE, Bart., F.R.S.

Surgeant-Surgeon to the Queen, and Surgeon to
St. George's Hospital.

GENTLEMEN,—There are very few departments of human knowledge which may not be cultivated, with more or less advantage, by those who are engaged in the pursuit of the medical profession. The phenomena of muscular action cannot be comprehended by one who has paid no attention to the study of mechanics. Without some acquaintance with the phenomena and laws of light, you will in vain endeavour to understand the physiology of the eye, and the treatment of its diseases. The classification of the various textures of the body; the changes produced in the animal fluids by respiration and secretion; the composition and exhibition of medicines;—these things must be altogether mysteries to those who have not applied themselves to chemistry. I cannot believe that any one is really qualified to undertake the management of cases of mania and imbecility of mind, who has not studied the mind in its natural and healthy state, and endeavoured to analyse his own intellectual and moral faculties. The stores of medical experience accumulated in former ages, and even the comparatively modern works of the great Haller, replete as they are with

the most interesting physiological information, are of little avail to those who have no knowledge of the dead languages.

It is not, however, my intention, in this introductory discourse, to enlarge upon these topics. There are some studies peculiar to the medical profession, to which, if you would do justice to the public, and obtain honour for yourselves, you must be especially devoted: which you must prosecute, not carelessly, and as a matter of form, but with zeal and unremitting diligence, through the whole period of what is called your education; and some of them also during the remainder of your professional lives. It is to the method of conducting these important studies that I am now anxious to direct your attention. My object is, in the beginning of your professional career, to place you in the right road; and I trust that the observations which I have to offer, founded as they are on experience, and on an earnest desire for your welfare, may not be unacceptable at the present time, nor be found altogether useless in the future.

In the practice of our art we undertake the cure of disease; and, in saying that we are to use our best endeavours, honestly and conscientiously, for the attainment of this object, we describe the entire duties of a medical practitioner. But for the cure of disease it is not sufficient that we should understand the nature and application of remedies; we must study disease itself, in all the variety of forms under which it may present itself to our notice. And this leads us to another order of inquiries. Disease is the derangement of one or more of the animal functions, in many instances attended with an alteration in the structure of the body; and, if you would understand these subjects, you must first make yourselves acquainted with the structure and functions of the body in its healthy state. Thus you will perceive what are the three principal divisions of

the course of education in which you are now engaged. The first comprehends the science of anatomy and physiology; the second that of pathology, or the science of disease; and in the third division we find whatever relates to medical and surgical treatment.

Let it always be borne in mind that this last is the real object which you have in view. I address you as future medical practitioners. If, taking another course, you choose to study anatomy and physiology, merely as interesting branches of human knowledge, you are at liberty to do so, and you will be as well rewarded for your labours as if you had applied yourselves to geology, optics, or astronomy. In like manner, if any one apply himself, as a philosopher, altogether to the study of pathology, he will find much in it that may interest himself, and that may be useful afterwards to those who carry their researches further. But as medical practitioners, you must not stop at either one or the other of these points; and, never losing sight of the ultimate object of all your investigations, you must estimate the value of whatever other knowledge you acquire, by the degree in which you find it to be directly or indirectly applicable to the healing art.

It is one advantage arising from the peculiar constitution of the London medical schools, that, with few exceptions, the instructions, which you here receive, have, in a greater or less degree, a tendency to practice. The ambition of the teacher of anatomy is not limited to success in his present vocation. He looks forward to the time when his profession as a physician or surgeon will elevate him to fame and fortune. His mind is naturally directed to those inquiries a proficiency in which will most assist him in the attainment of these objects; and that which is useful to himself cannot fail to be useful to his pupils. I have no doubt that the praises which are bestowed on some of the continental anatomists are well founded: that there are universities in which the anatomical professors, devoting their whole time, and industry, and intellect, to this one pursuit, explain the mysteries of minute anatomy at greater length, and with more precision, than the teachers here: but, nevertheless, I assert that ours is the better method with a view to the education of those who wish to become, not mere philosophers, but skilful and useful practitioners.

In like manner, pathology is not taught here as a separate science, but you receive your instructions in it from the lecturers on the practice of physic and surgery, who, while they explain the changes of function or structure, which constitute disease,

point out also the symptoms by which the existence of these changes is indicated in the living body, and the means to be employed for the patients' relief. Thus while you are taught pathology, you are taught also its uses and application; and these different subjects, brought under your view at the same time, serve mutually to elucidate each other; for, while pathology assists you in obtaining a knowledge of symptoms, the study of symptoms, and of the operation of remedies, contributes in no small degree to extend your knowledge of pathology.

The education of a medical practitioner, for whatever department of the profession he may be designed, necessarily embraces a variety of subjects. But it is extended over a space of at least three years, and it is of great importance that you should so arrange your studies that no excessive and overpowering demand may be made on your attention at any one period. And here let me advise you to begin with a system of steady application, and to adhere to it throughout. It is not uncommon for medical students, any more than it is for other students, to engage at first with zeal in their pursuits; then, as these lose the charm of novelty, to become careless and indifferent, and at last, when their education is drawing to a close, and it becomes a question how far they are qualified to undergo the required examinations, to endeavour to make up for the time which has been mis-spent and wasted by excessive labour, such as is incompatible with sufficient physical repose and mental relaxation. But it is not in this way that great things are to be accomplished, either in our profession or in any other. Habits of attention which are once lost are not easily regained: and no durable impressions are made upon a mind which is exercised beyond its powers. The slow but persevering tortoise reached the goal before the hare, who was over-confident of the speed which she could exercise if she were required to do so; and this fable, which we were taught in the nursery, conveys a moral lesson which the philosopher need not be ashamed to learn.

The studies which will occupy the principal part of your time are those of anatomy, and of the hospital practice; and you cannot doubt as to which of these has the claim of precedency. I will not say that a student who attends the wards of the hospital in the beginning of his education may not thence obtain some sort of useful practical knowledge; but it is plain that he can profit little by it, compared with one whose mind has been prepared by a previous diligent attendance on the anatomical lectures and dissecting-room. The attendance on anatomical lectures is

necessary for your initiation into the study of anatomy; they give you a general view of what you have to learn, and are, at the same time, the source whence you will derive your principal instructions in physiology. For anatomy and physiology are one science, and to teach them separately is about as absurd as it would be to divide astronomy into two sciences, the one teaching the figure and size of the heavenly bodies, and the other their motions. But to be a good anatomist, the student must labour in the dissecting-room; he must unravel the structures of the human body with his own hands, and examine every thing for himself. The impressions which dissection leaves upon his mind not only are accurate, but they will be lasting: if he trusts to those which he receives from the discourses and exhibitions in the lecture-room, he will find them to be evanescent.

Such is the connexion of the different parts of the animal system, and so dependent are they on each other, that it would be hazardous to regard the knowledge of any one of them as altogether useless. But there are some parts of which a general knowledge is all that is required. It would be an unprofitable waste of time to trace all the artificial divisions which may be made of the deep-seated muscles of the spine, or the varieties which occur in the minute ramifications of the veins and arteries. On the other hand, there are some parts, such as the bones and muscles of the extremities, the distribution of the principal nerves and larger vessels, the structure of the viscera, which cannot be too sedulously and minutely studied; and no one is fitted to undertake the practice of operative surgery who is not familiar with the exact relative situation of the parts concerned in surgical operations.

During the first season of your education, you will find that the labour of acquiring a competent knowledge of anatomy is such that you will have but little time to bestow on other studies. The few among you who have the opportunity of remaining in the schools during a period of five or six years, may do well to devote even two entire winters to anatomy before they begin their attendance on the hospital practice. But I cannot give this advice to the majority of those whom I now address, and whose period of education is more limited. And here let me observe, that it is a great mistake to suppose, after the first anatomical session is over, that it is better for you to defer beginning your attendance on the hospital until the next autumn. You will, in fact, attend the hospital to greater advantage during the summer than at any other time. The

same opportunities of experience present themselves at the hospital at one period as at another, and during the summer you can bestow a more undivided attention on what there occurs, than you can during the winter.

While engaged in attendance on the hospital, always bear in mind that there is no one of your other studies which, as to real importance, can compete with this. The lectures on anatomy, chemistry, materia medica, practice of medicine and surgery, and midwifery, are nothing in themselves. They are but the means to an end, and are valuable only because without them you would be unable to learn the symptoms and treatment of diseases in the hospital. I feel it my duty to make this observation, and to make it earnestly, because it appears to me that the truth which it inculcates is not, for the most part, sufficiently impressed on the minds of medical students. Perhaps, however, if strict justice were done to all concerned, and we were to trace this mistake to its origin, we should find that it belongs, not so much to the medical students themselves, as to those by whom their course of education is regulated, and who, by a false estimate of the importance of lectures, and an unnecessary multiplication of the number of them which the students are required to attend, have left an altogether insufficient time for a profitable attendance on the hospital.

Indeed, it is not by going through the form of walking round the wards daily with the physician and surgeon that you will be enabled to avail yourselves of the opportunities of obtaining knowledge which the hospital affords. You should investigate cases for yourselves; you should converse on them with each other; you should take written notes of them in the morning, which you may transcribe in the evening; and in doing so you should make even what are regarded as the more trifling cases the subject of reflection. Some individuals are more, and others are less, endowed by nature with the power of reflection; but there are none in whom this faculty may not be improved by exercise, and whoever neglects it is unfitted for the medical profession.

You will at once be sensible of the great advantage arising from your written notes of cases. But that advantage is not limited to the period of your education. Hereafter, when these faithful records of your experience have accumulated, you will find them to be an important help in your practice; when years have rolled over you, and the multitude of intervening events has obscured the once bright inscriptions on your memory.

Feeling as I do how essential it is, both

to yourselves and to the public, that your hospital studies should be well conducted, I shall proceed to offer some further observations on this subject.

In the first instance, your attention should be directed more to the symptoms and progress of diseases than to their treatment. You should begin with those of the simplest form, as the only means of obtaining that elementary knowledge, without which you will in vain endeavour to comprehend the more complicated and difficult cases. Carrying with you into the wards of the hospital the knowledge which you have acquired in the dissecting-room, you will, in each individual case, make these inquiries:—What is the nature of the disease, considering it anatomically and physiologically, and in what organ is it situated, or has it no distinct locality? If these points can be satisfactorily determined, you will, in most instances at least, have discovered the bond of connexion between the various symptoms; your subsequent investigation of the case will be rendered more simple; and you will be enabled to form a more distinct and rational notion as to the treatment which is required, and the probability of a cure, than you could have formed otherwise. Do not be satisfied with having learned the structure and functions of the body in health, but attend the examination of those who have died of their complaints; and endeavour to associate the symptoms which existed before death with the morbid appearances observed afterwards. The more extended cultivation of morbid anatomy is one of the most peculiar features of modern times. It has laid the foundation of a more accurate system of pathology than that which existed formerly, and has led to many improvements in practice; and it is right that your minds should be impressed with a just sense of its great value and importance.

Having said thus much, I trust that I shall not be considered as under-estimating these researches, in the observations which follow. Morbid anatomy is not pathology, though it is an essential part of it. You may know all that is to be known of the former, and yet your knowledge of the latter may be very limited. To be a pathologist you must study disease in the living body, even more than in the dead. Even in the instance of what we call local diseases, morbid anatomy does not teach us all that we ought to know; but there are many diseases which, as far as we can see, have no absolute locality; and what does it teach us there? In cases of hysteria, gout, fever, and in a number of others which it would be easy to enumerate, the dissection of the dead body furnishes us with little else than negative in-

formation; and in some cases, if we trust implicitly to it, morbid anatomy will prove a deceitful guide. Thus, in a patient who has died of continued fever, you find the mucous membrane and glands of the lower portion of the small intestine ulcerated. Your first impression might be that you had discovered the original malady of which the fever was symptomatic. It is only by the investigation of the disease in the living person that you are enabled to satisfy yourselves that the ulcers were the consequence, and not the cause of the fever. The mere morbid anatomist may suppose that in the inflammation of the œsophagus and trachea, he has discovered the essence and real seat of hydrophobia; but a more extended observation teaches you that such inflammation is but a contingency; and that whether it exist in a greater or less degree, there will be the same fatal termination of the patient's sufferings. Then there is an extensive class of diseases in which we may say that there is actually no danger; and of these morbid anatomy can teach us nothing, although we may learn much respecting them, so as to understand their nature sufficiently well, by investigating them in other ways. We know as much of a sick headache as of pulmonary consumption; as much of psoriasis and lepra, as of small-pox and measles.

If you were to trust implicitly to what is taught in books and lectures, you would suppose that you must understand the nature of every case that you meet with, and be able to give it its appropriate appellation. But a very little experience in the hospital will teach you that it is not so in reality. No fault is to be attributed to authors and lecturers; for if they were to attempt to teach the science otherwise, they could not teach it at all. But you must take care that you are not misled, and be prepared to meet with cases of which the nature is doubtful, and even with some which are absolutely unintelligible. Never allow your imagination on these occasions to supply the place of knowledge. It is something to be aware of our own ignorance, which time and observation and reflection may remove, but which is likely to be permanent if we think it necessary to offer a hypothetical explanation of every case which we do not, in the first instance, comprehend.

Although, as I have already observed, the symptoms and progress of diseases claim your first attention, yet you will soon discover that these cannot, in practice, be separated altogether from the study of the means to be employed for their relief; and you must, at an early period of your attendance at the hospital, endeavour

your to form some notion of the principles on which the latter is to be conducted.

The first question, then, which should present itself to you in the management of a particular case, is this:—Is the disease one of which the patient may recover, or is it not? There are, indeed, too many cases in which the patient's condition is so manifestly hopeless that it is impossible for you to overlook it. Let me, however, caution you that you do not, in any instance, arrive too hastily at this conclusion. Our knowledge is not so absolute and certain as to prevent even well-informed persons being occasionally mistaken on this point. This is true, especially with respect to the affections of internal organs. Individuals have been restored to health who were supposed to be dying of disease in the lungs or mesenteric glands. But it is also true, though to a less extent, with respect to diseases of parts which are situated externally. I know females who are now alive and well, who were supposed to labour under malignant disease of the uterus; and I could mention many cases in which patients have recovered of what had been regarded as an incurable disease of a joint. It is a good rule in the practice of our art, as in the common affairs of life, for us to look on the favourable side of the question, as far as we can, consistently with reason, do so. A sanguine mind tempered by a good judgment is the best for a medical practitioner. Those who from physical causes or habit are of a desponding character, will sometimes abandon a patient to a speedy death, whom another would have preserved altogether, or for a considerable time.

There is another inquiry which should be always made before you determine on the adoption of a particular method of treatment. What will happen in this case, if no remedies whatever be employed? If the patient be left altogether to nature, or to the efforts of his own constitution? There are many diseases which, for the most part, undergo a spontaneous cure, and we should be always very cautious how, in such cases, we disturb the natural process. A prudent physician watches a case of measles or small-pox, but it is only on some special occasions that he ventures to have recourse to any active remedies. The surgeon ought to be influenced by similar views in the management of the cases which come under his care; those, especially, in which the patient suffers from the effects of mechanical injury. The animal system is not like a clock or a steam engine, which, being broken, you must send to the clock-maker or engineer to mend it; and which cannot be repaired otherwise. The living machine, unlike the works of human invention, has the

power of repairing itself; it contains within itself its own engineer, who, for the most part, requires no more than some very slight assistance at our hands. We bring the edges of a wound into contact, but the vascular union which constitutes the healing by the first intention, is the work of a higher art than any that we profess to practise. If this mode of union fails, and the wound is to be healed by granulation, still this is not accomplished by our means. So where there is a simple fracture, all that we can do is to place the two ends of the bones in a proper position, and keep them in it. The process by which they are made to unite, so as to be again consolidated into one bone, is not under our dominion and control. These are, it is true, examples of slighter and simpler injury; but even in those in which the injury is more severe and complicated, it is easy for us to interfere to the patient's disadvantage, and, in fact, it may be truly said, that there is, on the whole, more harm done by too much than there is by too little interference. A patient with a compound fracture of the leg, or a wound of the knee-joint, stands a comparatively bad chance of recovery, if the surgeon, in his daily visits, disturbs the position of the limb, introducing his probe into the wounds and sinuses, and dressing them to the bottom with lint. Wounds of the brain are, as you must already know, highly dangerous, so that there is only a small proportion of recoveries among a great number of deaths from these accidents. I was once at the trouble of looking over all the cases of this kind which I could find recorded among my own manuscript notes, and in what might be regarded as standard books belonging to this part of surgery. I constructed a table, which represented, in every case, the kind of wound, the treatment employed by the surgeon as far as operations were concerned, and the results which followed; and it was curious to observe how large a proportion of the recoveries occurred in those cases in which the surgeon either avoided an operation altogether, or confined himself to the removal of some loose and detached pieces of bone. You may well suppose that a person who has a musket-ball lodged in the brain is in a very dangerous condition; nevertheless, it appears that it is safer to allow it to remain, than to endeavour to extract it.

I feel it my duty to give you these cautions. I should, however, be sorry if, in so doing, I were to lead you to overestimate what nature can do, or to underestimate the resources of our art. No one will probably be bold enough to tell you that surgery is useless; and none but the

ignorant will hold this language respecting the sister art of medicine. You will not have been engaged for two months in visiting the bed-sides of the patients in the hospital, without having ample means of contradicting this absurdity. I said that it is easy to interfere too much in the management of a case of compound fracture; yet the life of a man who has met with such an accident has been frequently preserved by the surgeon seizing a fit opportunity to open a putrid abscess. I said that a prudent physician, called to a case of measles, will do little more than watch the progress of the disease where it proceeds favourably; but its symptoms of pneumonia shew themselves, and blood-letting is not resorted to at a proper period, the death of the patient may be the consequence of such neglect. When I tell you that we are to trust to nature, I do not mean to say that we are to confide in her altogether, but that our rule should be not to disturb her operations without an adequate reason for so doing; at the same time holding ourselves ready, where a just occasion presents itself, to step in to her assistance, and then act with promptness and decision.

You will soon learn that it is not equally easy, in all cases, to determine what is the mode of treatment most calculated to be useful to the patient. The disease may be simple and obvious, so that no doubt can be entertained respecting it; and we know if any remedies which we possess are capable of relieving it, and what they are; and if it be not under the influence of remedies, we know that also. But in another case, the disease may be complicated, the complication being, most usually, of this kind; that, that which most attracts our notice is not the primary disease; but it is against this last, and not against the diseases that follow in its train, that our remedies are to be directed. Bearing this rule in your minds, you will understand many things that occur in the hospital, which you could not have understood otherwise. A patient, for example, has his legs swollen from anasarca; the skin tense, inflamed, and likely to give way and ulcerate, or even threatened with gangrene. We make punctures with a needle: the fluid escapes, the tension is relieved, the inflammation subsides. But the relief is only temporary. The swelling depends on an obstruction to the return of the venous blood from the limb, produced by disease elsewhere, probably at a considerable distance from the part to which our attention has been principally directed. To prevent a recurrence of the mischief in the legs, we must endeavour to remove, or, if that cannot be accomplished, to palliate, the original disease. Another patient suf-

fers from inflammation of the synovial membrane, which lines the knee. The joint is painful, and distended with fluid. Perhaps we are told a history of some sprain; but on inquiry it is evident that the accident was so slight, that it will not account for the symptoms. We have recourse to leeches, blisters, and liniments, and keep the limb in a state of repose; but although somewhat mitigated, the inflammation still lingers in the joint. In fact, we have not yet traced the disease to its origin. On further inquiry we find that there is a faulty digestion, with flatulence and acidity of the stomach after meals, and a copious secretion of lithate of ammonia by the kidneys. In addition to our other remedies, we administer magnesia, small doses of mercury, and perhaps colchicum, and the disease subsides.

Again, a case, whether simple or complicated, may be obscure; so that we cannot well satisfy ourselves what the symptoms indicate, or how they are linked together. Here we can do nothing better than consider what are, on the whole, the most reasonable explanations, which can be offered of the circumstances of it; and without adopting these explanations as realities, our practice must be a series of experiments founded on them. If our first experiment should not succeed, in our second or third we may be more fortunate; and in the meantime, every one of them probably gives us a clearer insight into the disease, so that we may proceed with more confidence in our treatment of it.

But let us suppose another case. A disease is so obscure, or so beset with difficulties, that we are absolutely at a loss how to treat it, having nothing to direct us in our practice. Here we may apply a rule, which is also applicable to all the concerns of life. When we know not what to do, it is better that we should do nothing. Nature may accomplish something for the patient; and if our efforts to assist her are founded on no principle, they are more likely to be mischievous than they are to be useful.

It is almost proverbial among us, and I have already expressed the same thing, though in other words, that our object should be to seek remedies for the disease, and not for the symptoms. But there are few general rules which are not to be received with some degree of limitation. Particular symptoms may be so urgent, that we must endeavour to relieve them at all events, without reference to the causes which produce them. You must, under certain circumstances, puncture anasarcaous legs, although this does nothing for the primary disease. The pain of the tic douloureux is merely a symptom, probably indicating the existence of some kind of dis-

ease in the brain: but if the patient be distracted by excessive suffering, are we not to administer opium for his relief? A physician is called to a patient with a weak and fluttering pulse, and cold extremities, who is, to use common language, in danger of sinking. He does not hesitate for one instant to give him ammonia and brandy, without waiting to inquire about the original malady. If the post-mortem examination should afterwards disclose that some internal inflammation had been going on at the same time, there is nothing for him to regret: a knowledge of that circumstance would not have altered his practice in such an emergency as this.

So far the rules of practice seem to be sufficiently intelligible. But the great difficulty remains to be noticed. How are you to determine what are remedies, and what are not, and the real value of the remedies which you possess? Here is the most abundant source of the errors which infest our art; from which even the most experienced and discerning practitioners are not altogether exempt, but which especially prevail among those who are deficient in experience or good sense. It is to the almost entire ignorance of the public, and especially of the more affluent classes, as to the evidence which is necessary to establish the efficacy or inefficacy of a particular mode of treatment, that we are to attribute the reputation which is frequently obtained by empirics and other adventurers, who pretend to practise the art, without having learned the science of medicine.

When the optician, in constructing an optical instrument, arranges his lenses and reflectors in a new order, his knowledge of the principles of optics enables him to predict the effect which will be produced, so that, except as to some minor circumstances, he can be scarcely said to be making an experiment. But there is no reason to believe that in the study of those varied and complicated phenomena which are the subject of physiology and pathology, we shall ever arrive at that point which has been long since attained in optics, and some other branches of natural philosophy; and at all events we are far distant from it at the present moment. Few greater benefits have been conferred upon mankind than that for which we are indebted to Ambrose Paré—the application of a ligature to a bleeding artery; but no knowledge which he possessed would have enabled him to say more than that it would be probably successful; and it was left for after ages to demonstrate the principle on which it acts, and to explain the circumstances which may cause its failure. John Hunter, as you will hereafter learn, was led by his knowledge of the animal economy to propose a new method of

treating aneurism; and it is impossible to estimate the number of lives which have been preserved by this discovery; yet it was but an experiment, of which even his philosophic mind could not with certainty predict the result. It must, however, be admitted, that science pointed out the road to these inventions. But this cannot be said of the great majority of the remedies which you will see employed. Nothing that could be known beforehand would lead you to expect that ipecacuanha would operate as an emetic, or that opium would occasion sleep—that quinine or arsenic would cure the ague—that inflammation of the iris would yield to mercury—or the gout to colchicum. The invention of these, and of a multitude of other remedies, is of accidental origin; we are indebted for our knowledge of them, for the most part, to the observations of ignorant persons, accumulated during a long series of ages; and the office of men of science is little else than to study their effects minutely, and to learn the right application of them. But even in doing this, the greatest caution and, I may say, scepticism, is necessary to prevent you being continually guilty of mistakes. I have already told you how many diseases, if left to themselves, admit of a spontaneous cure. We see the surface of the body, and we know, by certain outward signs, a good deal of what takes place within; but there is much of which we know nothing, so that it is impossible for us to take cognizance of all the circumstances which may occur to modify the course and alter the termination of a disease. If we always yield to the instinct which inclines us to believe that when one event follows another, the first is the cause, and the second the effect, we shall be frequently directed wrong. The fact of a patient having recovered under a particular mode of treatment goes but a little way towards establishing its value; nor is any thing sufficient for this purpose, short of the same result being obtained in many similar cases, in which there was otherwise little prospect of recovery. It is the disposition of every one of us to admit the efficacy of the remedies which we employ on insufficient evidence; and unless we, whose duty it is to understand these subjects, are on our guard against this not unnatural prejudice, we have little right to blame the credulity of those whose minds are not turned to these inquiries, when a corresponding error of judgment leads them to believe in the absurdities of metallic tractors, animal magnetism, and homœopathy!

But there are still further considerations, which must not be overlooked in this part of our inquiry. It is not enough that you should have satisfied yourselves, by your own observations, or by those of others, as

to the efficacy of a particular remedy in a particular disease: you must look further still; endeavouring to learn what such a remedy may do besides. That which is usually an agent for good, may, under certain circumstances, be an agent for evil also; and as the habits and constitutions of individuals differ, so it is not always in your power to foresee which influence will predominate. Each individual case must be separately and carefully studied, while under treatment, and with a view to its treatment, as much as with a view to a true diagnosis in the first instance. Arsenic is a remedy for *lepra*. Most persons can take it in the doses necessary for the cure of that disease, without experiencing the smallest inconvenience from it; but, in some, a very moderate dose will operate as a poison. Here, by watching its effects, you will always be enabled to discontinue it in time to prevent any ill consequences arising from it; and the fact of it disagreeing with one person, does not therefore prevent you giving it to another. But in other cases the circumstance of a method of treatment which is generally useful, being occasionally injurious, is a sufficient reason for you to lay it aside altogether. A late eminent surgeon proposed the ligature of the principal vein on the inside of the leg, as a remedy for varicose veins and ulcers of the limb. For some time the operation seemed to be attended with the best results; but ultimately it was ascertained that inflammation, of the membrane lining the vein occasionally followed. Such inflammation, when once established, is often uncontrollable, and always highly dangerous; and the possibility of its occurrence is more than sufficient to counterbalance all that can be said in favour of the operation.

I fear that, in my anxiety to give a right direction to those studies, which, as I believe, constitute the most important part of your education, I am already beginning to exceed the brief limits of a lecture. There is, however, one other subject which will not detain you long, and on which, before we part, I feel it my duty to offer a few remarks.

As medical students, you have little leisure for reading; you must, however, be provided with some good systems of Anatomy and Physiology to assist you in the dissecting-room; and you will find some of the best modern compilations relating to Medicine and Surgery useful when you begin your attendance on the hospital. There are some few books which you ought carefully to peruse. I leave it to the different lecturers to point out what they should be; but I shall take upon myself to mention as one of them the Treatise of John Hunter on the Blood and Inflammation. It is true that the essential parts of John Hunter's doc-

trines as to inflammation and its consequences are now so incorporated with what is taught in schools, that to be acquainted with them you need not seek them in his works: but I recommend you, nevertheless, to make these your especial study, for the sake of the other valuable information which they contain, and the important views in physiology and pathology which, in almost every page, are offered to your contemplation; and also for this reason, that they will improve your faculty of observation, and furnish you with materials for reflection during the remainder of your lives.

During the latter period of your attendance on the hospital, and afterwards, when first engaged in practice, you should be provided with what may be regarded as the standard works on Pathology, Medicine, and Surgery. Not that I mean much to recommend a course of medical reading, which for practical purposes is nearly useless. Books should be had recourse to chiefly for the purpose of reference, when circumstances have brought a particular subject under your observation. And here I must advise you not to confine yourselves within the narrow bounds of modern publications; an error which is, I fear, too common, at present, not only with medical students, but with practitioners. It is true, that within the last fifty years a vast impulse has been given to our sciences; but it is equally true that they were cultivated not unsuccessfully before. There is no richer mine of surgical knowledge than that which is contained in the memoirs of the French Academy of Surgery; and, as far as I know, there are no descriptions of disease more accurate and graphic than those which have been bequeathed to us by Sydenham.

Gentlemen! Although many years have since elapsed, it seems to me but as yesterday, when I was, as you are now, a young adventurer in this great metropolis; and I well remember how often, in the intervals of my occupations, I have contemplated, with something like dismay, the prospect which lay before me. My own feelings, at that time, explain to me what may possibly be yours at the present moment. Yet you have undertaken nothing which energy and perseverance, and upright and honourable conduct, will not enable you to accomplish. It cannot, indeed, be predicated of any individual to what exact extent he may attain professional success, for that must depend partly on his physical powers, partly on the situation in which he is placed, and on other contingencies: but having had no small experience in the history of those who have been medical students, I venture to assert, that no one who uses the means proper for the purpose will fail to succeed sufficiently to gratify a

reasonable ambition. You have entered on pursuits of the highest interest, in which you will have the no small satisfaction of knowing that you never acquire any real advantage for yourselves which is not the consequence of your having benefited others. It is true you have years of constant exertion before you; but you will eventually learn how preferable such a situation is to that of those individuals who, born to what are called the advantages of fortune, but neglecting the duties of their station, believe that they can direct their minds to no more worthy object than the multiplication of their selfish enjoyment. It will not be your lot, as it is often theirs, to suffer the miseries of ennui, or to be satiated and disappointed with life at an early period: nor will you have to regret, as you advance in age, that you have lived unprofitable members of society. It is also true that you will meet with difficulties in your progress: but there is no higher gratification than that of surmounting difficulties; and whenever they occur you will be cheered by the anticipation of that period when you may look on past events, and say to yourselves—

“*Multa dies variusque labor mutabilis ævi
Retulit in melius.*”

CLINICAL LECTURES ON MEDICINE,

Delivered at the Meath Hospital, Dublin,

Session 1837-8,

BY PROFESSOR GRAVES.

LECTURE V.

Burdock on Impetigo.—Dr. Roe's Report on Syphilis.—Treatment of Gonorrhœa.—Mr. Hoskins on Purulent Ophthalmia.

GENTLEMEN,—I had recently under my care a young man who suffered greatly from an impetiginous affection, accompanied by varicose veins of the legs; the tibial surfaces of both were covered with ulcers, from which a considerable quantity of purulent and ichorous fluid exuded; and as his business obliged him to walk about constantly, he suffered a great deal of distress and annoyance. I treated him, at first, with leeches and poultices, and afterwards with various astringent applications, but with very little relief; the discharge from the legs was profuse, and the heat, itching, and soreness undiminished. While in this state, he was advised by a friend to take about four or five ounces of burdock root (*Aretium Lappa*), and having boiled it in a quart of water down to a pint, to drink this quantity of decoction every day in divided doses. He did so, and in the space of three or four days a most remarkable improvement took place.

Thinking that the benefit derived might be the result of accident, I made him leave off the burdock for a few days, and found that the legs began to get bad again. He resumed the use of it, and is now well. I do not wish to attach more interest to this case than it deserves; but certainly, the decoction of the burdock root operated in a very remarkable manner in improving this gentleman's health, checking the tendency to impetiginous inflammation, and arresting the profuse discharge. Here is a specimen of the root itself—although it is not at present mentioned in our pharmacopœia, it held a place at one time in the *materia medica*, and enjoyed considerable reputation as an alterative remedy.

I shall now, gentlemen, proceed to lay before you some observations on syphilis. Bell, Hunter, Matthias, Pearson, Carmichael, Rose, Hennen, Colles, Wallace, and Ricord, have so diligently investigated the history, symptoms, and special pathology of venereal affections, that I consider it unnecessary to touch upon these matters, at present, and consequently I mean to confine my remarks to a few controverted subjects connected with the general pathology and therapeutics of syphilitic diseases.

I hold in my hand a report, by my friend Dr. Roe, containing a return of the venereal patients treated in the 38th Regimental Hospital, from the 11th of June, 1836, to the 15th of November, 1837; giving in separate columns the names, ages, forms of disease, periods of admission and discharge, duration of the treatment, and remarks. The compiler, Dr. Roe, was a fellow student of mine, educated in Dublin, and always noted for his intelligence, accomplishments, and steadfast zeal for his profession. Under Dr. Colles, and the surgeons of the Lock Hospital, he had ample opportunities of witnessing the effects of the mercurial treatment of syphilis. He has treated the disease in the East Indies, the Ionian Isles, and at home, and from his habits of observation, sagacity, and attention, any statement coming from him must be very valuable. During the period from the 11th June, 1836, to the 15th of December, 1837, the number of patients treated in the hospital of the 38th regiment was 231. Of these, 80 were affected with gonorrhœa, 87 with chancre, 36 with bubo, 23 with hernia humoralis, and 4 with chancre and bubo. 90 were under 20 years of age; 95 from 20 to 25; 23 from 25 to 30; and 17 from 30 to 40 and upwards. Several caught the infection more than once during the space of time mentioned. Thus, Henry Carter was admitted for gonorrhœa on the 11th of June, 1836; again for gonorrhœa, on the 25th of February, 1837; and again for the

same on the 4th of May, 1837. John Adams, twice for gonorrhœa; Arthur Nesbitt, twice for chancre; John Williams, twice for chancre; William Bexham, twice for chancre; John Jess, once for gonorrhœa, and a second time for bubo. With respect to the duration of these cases, treated wholly without mercury, Dr. Roe gives the following summary:—The cases of gonorrhœa were on an average 15½ days under treatment; chancre, 21¼ days; bubo, 27¾; swelled testicle, or hernia humoralis, 11¾; severe cases of chancre with bubo, 18¼ days. The following was the general plan of treatment pursued by Dr. Roe, and first with regard to gonorrhœa. The men on admission, having been washed with warm water and soap, were ordered to take an aperient mixture, composed of sulphate of magnesia and tartar emetic, every third hour, until the bowels were freely opened. A small piece of lint was applied to the orifice of the urethra, and a short roller soaked in cold water was passed round the penis, to keep the parts cool and clean. If there was much ardor urinae, the patient was ordered to foment the part, and syringe with warm water every second hour. As soon as the ardor urinae abated, an injection of sulphate of zinc (gr. ij ad ʒj. aquæ) was used four or five times a day; as the smarting in passing water abated, the proportion of sulphate of zinc was increased to five grains to the ounce. He then commenced bathing the parts with cold water, and took balsam of copaiba, turpentine, or cubebs. The patients were invariably confined to bed while under treatment, used only spoon meat or milk diet, and barley water for drink. Every third or fourth morning a dose of Epsom salt, with or without tartar emetic, was taken to keep the bowels free. In a few obstinate cases, injections of sulphate of copper or nitrate of silver were employed, with the occasional use of the bougie, or a small blister over the track of the urethra.

From this simple but excellent and efficacious plan of treating gonorrhœa we come now to the treatment of chancre. This is a point deserving of your attention, and peculiarly important with reference to the subject at present under consideration. The patients, on admission, were purged with Epsom salt and tartar emetic, and were ordered to apply a bit of lint wet with a solution of sulphate of copper to the chancre, renewing the application every second hour, and using the moistened roller to keep the parts cool and retain the dressings. Milk diet was prescribed as before, and a dose of salts, or salts and tartar emetic, taken every second morning. The parts were frequently bathed with cold water, particularly if there was any pain in the groins,

and the chancre were occasionally touched with nitrate of silver, or sprinkled with red precipitate to expedite the cure. Calomel was rarely given; and when administered, not for the purpose of affecting the mouth, but merely as an alterative, and in combination with tartar emetic. The men were all confined to bed, the most perfect cleanliness insisted on, and the bowels kept in a soluble state.

Buboes were treated in a similar way, but with a more rigid observance of the antiphlogistic regimen. Buboes are often seen without any ulcers on the penis, or they have appeared after the ulcers have healed. They were constantly bathed with cold lotion, and by this means, aided by the solution of tartar emetic and salts, they were frequently dispersed. If, in spite of these measures, they become enlarged, red, and tender, a warm poultice, three times a day, and frequent fomentations, were employed. If there was still any chance of resolution, small doses of calomel and tartar emetic were administered, and the poulticing continued, care being also taken to keep up a loose state of the bowels by saline purgatives. In general, these means were followed by the desired effects. If, notwithstanding these measures, the buboes increased in size, became softer, and exhibited proofs of fluctuation, Dr. Roe opened them by applying the *kali purum* to the diseased surface. He then continued the fomentations and poultices, dressed the ulcer with red precipitate, and when it began to assume a healthy appearance, applied a compress and roller to keep the edges of the ulcer together, and keep down exuberant granulations. At the same time the patient took decoction of bark with sulphuric acid, or sarsaparilla with nitric acid; these, with a more generous diet, and a moderate use of porter, generally succeeded in producing a speedy and permanent cure.

Among all Dr. Roe's patients there was only one case of secondary syphilis. This man, who laboured under buboes at the time of his admission, was in bad health; the buboes were extremely chronic, and difficult of cure. He was treated during the winter, and returned, sometime after being discharged, complaining of cough and sore throat, with a papular eruption over the breast, back, and thighs. He was treated with alterative doses of calomel, combined with tartar emetic and opium, and used the warm bath three times a week. His bowels were kept open, a generous diet, with porter, was allowed, and he took the decoction of sarsaparilla with nitric acid. He recovered completely, and is now stronger and in better health than he has been for many years. A solution of alum, as a gargle, and the use of

volatile liniment, with flannel, externally, was all that was found necessary for the cure of his sore throat. He was about a month under treatment.

Such was the plan of treatment followed by Dr. Roe, and that it proved eminently successful is shewn by the result, for out of 231 patients, of whom 87 had chancre and 36 bubo, there was only one case of secondary syphilis. Of these facts I have been myself a witness, and they are certainly of great importance. I do not think that more gratifying results could have attended the best-regulated mercurial treatment. I may observe, however, that soldiers enjoy many advantages which civilians of the humbler class are, in a great measure, deprived of. They are not left to their own discretion as to the time they should apply for advice, or to the mode in which they should conduct themselves during the course of treatment. Soldiers are generally inspected by the medical officer once a week; the glans, prepuce, orifice of the urethra, and groins, are carefully examined, so that any trace of disease cannot escape detection.

In this way the disease is attacked at its very commencement, and checked at once; a circumstance which, for reasons hereafter to be explained, has an important influence on the proportion of the cases of secondary syphilis.

Again, during the process of cure, the men are not allowed to walk about, take exercise, indulge in the use of intoxicating liquors or stimulant diet, or expose themselves to the vicissitudes of the season. It may be also observed, that soldiers, from the care employed in the selection of the recruits, from their mode of life, diet, exercise, and regular hours, are some of the healthiest members of the community; and therefore enjoy, in a very remarkable degree, the advantage of resisting infectious diseases, or getting rid of them sooner than persons of feeble constitution.

There are some points in Dr. Roe's treatment to which I shall now advert. In gonorrhœa he begins, internally, with cooling antiphlogistic medicines, and afterwards passes to the use of internal stimulants. He also applies local antiphlogistic means in the commencement, directing the patient at first to syringe with tepid water, which is exchanged for a mild astringent injection as soon as the ardor urinæ abates; and he afterwards employs stronger and more astringent injections. When neglect or an injudicious treatment have allowed gonorrhœa to attain the second stage—that of inflammation, it will be always right to apply the antiphlogistic method generally and locally; but this does not preclude the use of injections: they must be skilfully administered, for

fear of injuring the inflamed urethra, and at first should merely consist of one drachm of mucilage dissolved in seven of water. After using this two or three times, one grain of sulphate of zine may be added. On the morrow and day after the same may be continued, and then it may be rendered more active by increasing the quantity of sulphate, and adding other matters, of which more hereafter.

In order to prevent you from misunderstanding my meaning, it is necessary to explain that gonorrhœa may be considered as exhibiting three different stages. In the first, immediately succeeding the period of incubation (during which the infection has as yet produced no perceptible symptoms), a very slight oozing of whitish mucus takes place from the urethra, and a little tingling is felt in that passage, whose mucous membrane then exhibits an incipient redness. No pain is felt in passing water. This stage seldom lasts more than two days; but occasionally it does. When the gonorrhœa is to be violent, it is of short duration; when mild, of longer. It passes gradually into the second or inflammatory stage, with its well-known *profuvium*, ardor urinæ, and other symptoms; and this again, in due time, is succeeded by the third stage, or that of decline. The first and last stages are peculiarly suited for the employment of astringent injections.

I do not know any practical point on which greater diversity of opinion exists than the administration of injections in gonorrhœa. In Dublin, students are generally taught that their use is improper and dangerous. The following are the chief objections to which they are said to be liable:—1st, They do not diminish the urethral inflammation though they dry up the discharge, and consequently they lay the foundation for stricture, or more immediately occasion the inflammation to descend along the urethra, until it extends to the membranous portion, the prostate, or even the bladder. 2dly, Their use renders swelled testicle and sympathetic bubo more frequent. 3dly, It is argued that the use of any measures, except such as are purely antiphlogistic, must be improper in a disease accompanied by so many indubitable signs of inflammation. Let us closely examine this last objection, and we shall find it to possess more apparent than real weight, for analogy proves that the principle on which it depends is by no means universally applicable, particularly in cases of specific inflammation. When surgeons placed their sole reliance on antiphlogistic measures, local or general, in the treatment of purulent ophthalmia, the results were truly disastrous; and however exhausted the patient became

from excessive bleeding by the lancet and leeches, aided by large and frequently-repeated doses of tartar emetic internally, the local inflammation proceeded in its rapid and destructive course, scarcely influenced, never effectually checked, by the treatment adopted. I have seen a man treated (in the Meath Hospital, by myself and the late able ophthalmic surgeon, Mr. Hewson) with bleeding, general and local, employed I might say to excess, and aided by rapid and profuse mercurial salivation: I have seen, in the patient referred to, both eyes destroyed by purulent ophthalmia in a few days. Not long ago I was called during the night to visit a young gentleman in a hotel; he had gonorrhœa, and went to bed without any complaint of the eyes, but was soon awakened by pain in the left eye. It was evidently purulent ophthalmia, and was cured in the course of a few hours by relays of leeches, and a strong sulphate of zinc collyrium, carefully applied. After thousands had lost their vision from the effects of this disease, it was at length discovered that some who adopted a totally different mode of practice, and who treated the purulent ophthalmia in its very commencement with strong astringent and corrosive applications, were eminently successful. This led many army surgeons, more especially Mr. Guthrie, to investigate the subject with care. You are aware of the important practical results at which he arrived, and of the great improvement which has consequently taken place in ophthalmic surgery, leading to the application of solid nitrate of silver, or its concentrated solution, of sulphate of copper, &c. &c. to the mucous membrane of the eye in the first stages of purulent ophthalmia—a mode of treatment which our predecessors would not have hesitated to pronounce most hazardous and destructive.

That astringent and stimulant collyria are applicable in the incipient stages of some other species of ophthalmia, as well as the purulent, is now familiarly known to surgeons. The following example of its utility occurs in a work lately published, on the Oases of the Libyan Desert, by Mr. Hoskins. It is necessary to remark, that the ophthalmia described by Mr. Hoskins, and so common both among the natives and foreigners in Egypt, is essentially a purulent ophthalmia, which, however, attacks with very different degrees of intensity, being in some mild and chronic, in others most acute, and suddenly destructive of vision.

“Nov. 5th, 1832.—I was confined to my tent the whole of this day by a painful attack of ophthalmia; and although in the morning it was very severe, yet by double doses of the contents of an inestimable

bottle I have nearly subdued it. As some of my readers may wish to know what this wonderful vial contains—what this infallible remedy for such a baneful complaint can be—I will tell the history of it, though I cannot fully gratify the desire of the curious. The purser of the French frigate, the *Luxor*, which was built for the purpose of removing one of the obelisks from Thebes, was the fabricator of this extraordinary water. He informed me, when in Egypt, that his father had been attached to Napoleon's expedition to that country, and had then discovered this miraculous cure. From fear of its being analysed, he had never allowed any person to possess more than a very small quantity; but he cured without fee all who came to him, Christian and Mussulman, French and English, Turk and Arab. When this liquor was applied in time, it was found always to stop the most virulent attacks of the disease, and generally relieved in a very few days even those who had been for several months martyrs to the complaint. A Turk, who had suffered for years, was completely cured in a fortnight; and in gratitude to his benefactor, gave him a horse richly caparisoned. The Frenchman's fame was spread throughout the country, and many came to him as far as from Kenh and Esneh. Even the surgeon of the *Luxor* was so sensible of the value of the remedy, and of its producing no subsequent bad effects, that he sent all the officers and men of the vessel suffering from that complaint to the purser, or to the *hakim* (doctor), as the natives called him. The application was easy to the *hakim*, but most painful to the patient. He let fall a single drop of the water on the ball of each eye, which immediately spread, and from its pungent nature caused, if much irritation existed, the most inexpressible torture. In twenty minutes or half an hour this pain subsided, and a little clammy matter was seen to ooze from the eye. The remedy, although violent, did not weaken the eye in the slightest degree, nor in any manner injure the sight. Knowing that I purposed to go into Ethiopia, the *hakim* had the kindness to sell me, for about its weight in gold, a small bottle of this water; but under the express condition that I would neither directly nor indirectly allow it to be analysed. He said that it was his intention to return again to Egypt, and that he expected to be able to make his fortune; but whether he does or not, I feel most grateful to him for having saved me from much torture, as I have often been obliged to have recourse to the water, and have kept my promise in not allowing it to be analysed. As this person has now left the country, and no further supply is to be

obtained, I prize the water most highly, and cannot afford to use it for the relief of mere strangers. The remedy which we generally find to succeed with the natives, when applied to by them, is sulphate of zinc in strong doses—ten grains being dissolved in an ounce of water, and a drop of this being put in each eye two or three times a day. This is by no means so certain a remedy as the hakim's water, but in nine cases out of ten I have found it to succeed. When, however, the inflammation and swelling are so great that the eyes are closed, *cupping* is the only effectual remedy. Mr. Ponsonby, who travelled with me in Lower Nubia, was attacked with this description of ophthalmia. He sent without delay for the hakim, alias barber, of a village. It was fortunate that the eyes of Mr. P. were quite closed, for had he seen the hakim he would scarcely have reposed sufficient confidence in his skill to submit to the operation. The man was actually in rags, and of the most unprepossessing appearance, without a single ray of intelligence in his countenance. His cups were made of the horns of a cow, and his instrument was an old razor, not so decent-looking nor so sharp as a tolerably good stick knife. I offered him a lancet, but he said that he did not know how to use it. Thinking that it would be less painful for Mr. P. to be scarified with a sharp than a blunt razor, I gave the man one of my own; but being unaccustomed to so fine an instrument, and not aware of the much less force it required than his own blunt knife, he cut too deep; I therefore thought it best to allow him to finish the operation in his own way. I must confess, indeed, that he did it very expertly, and I may add successfully; as he effected a very sudden and almost miraculous cure of Mr. P.'s ophthalmia. At Thebes I had two severe attacks of this disease, which incapacitated me from either reading, writing, or drawing. Thanks to the hakim's water, these attacks were fortunately short; but they were painful while they lasted, and most irksome to support. To be debarred from all mental enjoyment and bodily exercise—to be in the world and yet see nothing; and to be without the general resources of the blind, particularly society, this was indeed tiresome. A Turk might probably have amused himself with his beads, but even a Mahomedan's philosophy would have forsaken him in such a situation, especially as the regimen necessary for this complaint requires the sacrifice of the all-consoling pipe. The Arabs and Turks having frequently asked me for medicine to relieve them from attacks of ophthalmia, the water that I applied to their eyes invariably caused them extreme pain;

which, however, they bore with great courage and resignation, having implicit faith in the skill of a European. When, however, I desired them to give up their pipes (smoking being extremely injurious) "Inshallah!" (please God!), they replied, but never had the resolution to do so. An opium-eater may refrain from his weed, a drunkard may resign his glass; but I soon found the absurdity of asking an Oriental to abandon his shibouk. Like ice to the Sicilians, macaroni to the Neapolitans, and grog to the British sailor, they consider it as their staff of life, and conceive it impossible to get through the day without it."

With respect to the objection that the treatment of gonorrhœa by injection lays the foundation for strictures, I beg most distinctly to deny the truth of the assertion: whatever diminishes the intensity, and shortens the duration of the urethral inflammation, must tend to diminish, and not to increase, the liability of strictures. Compare the violence and duration of a gonorrhœa skilfully treated from its very beginning, by injections, with a case where no injections are employed—the physician's reliance being exclusively placed on perfect rest, confinement, fasting, and cooling medicines; compare two such patients, observe how the one is perfectly cured of his disease in a few days, without confinement, and without any deviation from his usual diet and habits (I speak now of two cases coming under treatment in a day or two after the appearance of the very first symptoms); and then watch the other through sufferings protracted week after week, until his constitution is debilitated by confinement and low diet: how often do we find the discharge from the urethra increasing daily, in spite of the general and local antiphlogistic remedies employed, until it is profuse in the extreme, and accompanied by great ardor urinae, painful erections, irritation of the bladder, and chordee. Now I will fearlessly assert that a medical man who gets the care of a *recent gonorrhœa in a healthy constitution*, is grievously to blame if he permits this series of bad symptoms to supervene. I do not deny that these symptoms will at length give way to the antiphlogistic treatment, leeches along the perineum, stupes, inunction of the skin covering the urethra, with mercurial ointment and belladonna, &c. &c. These remedies will in the end get rid of the disease, but then at what a loss of time and strength! I again repeat the assertion, and I do it emphatically, that a gonorrhœa treated by injections *from the beginning*, can generally, in persons of sound constitution, be cured in a few days. When a gonorrhœa

has been allowed to continue several weeks, it often so alters the vitality, and probably the structure of the affected tissues, that a cure is uncertain, and frequently the treatment becomes both perplexing and tedious; when a gleet supervenes, then remedies even the most judiciously selected frequently fail altogether: these facts prove the necessity of curing the disease, in every instance, as soon as possible.

But, gentlemen, we must here enter into details, and first as to the manner of injecting the urethra. Many believe that the inflammation produced by the specific poison of gonorrhœa is seated chiefly, if not exclusively, in the portion of the urethra near the orifice; and hence they are only anxious to introduce the injected fluid a short distance in that canal. Nothing can be more unfounded than this opinion, and nothing more injurious than the practice to which it gives rise. The inflammation which gonorrhœa produces in the urethra is by no means confined to the third of the canal near its orifice, but even in recent cases it extends much farther, and it cannot therefore be efficiently treated by injections, which do not come into contact with the whole extent of inflamed surface. Unless you yourselves teach your patients how to inject, not one in ten of them will do it properly. Of this, an extensive experience has convinced me. Over and over again have I been told that there was no use in trying injections in a particular case, as they had been already tried in vain; and on accurately inquiring into the patient's mode of injecting, the result has been the discovery that he was quite ignorant of the proper method. The pewter syringe or squirt used must be in proper order, so as to work easily with the pressure of one finger; otherwise when the end is in the urethra, and the patient tries to inject the fluid contained in the syringe, the point is very apt to be hitched against the urethra, in consequence of the force thus suddenly applied. The point of the syringe must be carefully introduced at least half an inch within the lips of the urethra, and the forefinger and thumb of the left hand must then be so applied as to press the lips of the urethra gently on the syringe, so as effectually to prevent the reflux and consequent escape through the orifice of the injected fluid. When the fluid is thrown in, the patient will feel it in the urethra, which it will gently distend as far down as the membranous portion, if a sufficient quantity be injected. Some persons have an idle fear about the ill consequences which would arise were any of the injection to arrive at the bladder. An ordinary pewter syringe does not

contain more than a drachm and a half, which is about the quantity required for one injection. When the fluid has been injected, the point of the syringe is to be withdrawn, and the lips of the urethra kept closed with the finger and thumb, for at least two minutes, when, the pressure being removed, the injected fluid will be thrown out from the urethra with considerable force, in consequence of the elasticity of that canal. These directions, gentlemen, are by no means unnecessary; indeed, I never treat a patient without seeing that he knows how to inject, for I find that many say they know the right method, who are quite ignorant of it, and who consequently do themselves more harm than good by making the attempt.

It is not my object to enter at present into the especial therapeutics of gonorrhœa, and consequently it would be foreign to my plan to speak of the various substances which may be used in injections; for an account of these I must refer to authors who have written at large on this subject. As a general rule, you ought to commence with weak solutions of the astringents you prefer, which solutions may be used five or six times a day, and may be daily increased in strength. *An injection should seldom be used so strong as to cause at the time any thing like severe pain of the urethra.* In this respect we must not closely imitate the example of *eye-waters*, such as that used by the Egyptian *hakim*. I have, indeed, often known very strong injections used at the first trial, and which, though they produced great pain for many minutes after their introduction, yet were very effectual in rapidly curing the disease, and that without any bad consequences. (This is more especially the case with nitrate of silver, which, although a powerful remedy, I have found unmanageable, and therefore not to be recommended.) Still, however, by far the safer and most prudent practice is to commence with astringent injections, so weak that, when used, they may produce merely a sense of titillation, or of very inconsiderable smarting. It is often difficult at first to hit off, if I may use the expression, the precise strength required; and therefore I always give my patients particular instructions, and desire them, if the injection is at all too irritating, to dilute it with water to the desired degree of strength. The sensibility of the urethra diminishes very rapidly when an injection of proper strength is applied to the inflamed surface, so that the solution may be daily rendered more astringent. I have told you that astringent injections are suited to every case of gonorrhœa at the commencement of the disease, and that, when properly used during the first, second, or

third day, they almost always cut it short. It is not so when the disease has attained its *acmé*, and the inflammation is at its height, accompanied by profuse discharge, chordee, &c. &c. Even then, however, injections properly managed will tend to assist the local antiphlogistic measures; but in such cases we must always commence by using mere mucilaginous warm water, and must add the astringents at first very sparingly, and must increase their proportions very cautiously. I omitted to observe, *that always, before using an injection, the patient ought to clear the urethra by voiding a little urine.* Such directions, gentlemen, may appear to many prolix and unnecessarily minute; but not knowing any author who has condescended to give accurate accounts respecting these matters, I have thought it my duty to lay them before you, being convinced of their utility.

Before I conclude, it is right to put you on your guard about the mischief which may ensue if you attempt to prescribe astringent injections during the secondary or inflammatory stage of gonorrhœa, without previously having ordered such general and local antiphlogistic treatment as is required to diminish the existing inflammation; nor will even this be sufficient to ensure success, unless you take care that your patient remains quietly at home for a few days, and observes a spare vegetable diet. A person who will not follow your directions in these matters, cannot use astringent injections during this stage of the disease with benefit or even impunity. In the first stage, and in the third, it is not absolutely necessary to enjoin rest and abstinence; it is, indeed, better and more prudent that the patient should remain in his room, and should observe low diet for a day or two; but in some cases this is impracticable, and then he must, as far as possible, avoid stimulant food and much walking exercise.

ON SCURVY.

EXTRACT FROM THE

REPORT OF DR. MURRAY,

Principal Medical Officer at the Cape of Good Hope.

[Continued from page 296.]

Memorandum respecting SCURVY, by Surgeon Laing, Officer of Health.

Cape Town, 1837.

AMONG those which touched here last year the vessel in which scurvy prevailed most was the "Coromandel,"

South Australian trader, with emigrants, a very fine ship of 662 tons, extremely roomy, and of great height between decks. She left the Downs on the 9th September, 1836, bound to the new settlement of South Australia, and arrived here on the 18th November, having had an average passage of 70 days. She had the proper complement of seamen, six cabin passengers, and 150 men, women, and children in the steerage; the "between decks," however, instead of being kept free and clear, was regularly boxed off, with a view to the greater comfort (?) and privacy of the married people, which doubtless prevented its proper ventilation, and *it was by no means kept clean.*

On the 24th October, having been only forty-five days at sea, scurvy was discovered to have broken out among the steerage passengers, and upon a strict examination at the time, twenty-eight cases, of different degrees of severity, were detected, which number gradually increased, and in the course of twenty-five days more, on the arrival of the vessel here, it had amounted to nearly eighty.

The females were the principal sufferers from it, and several of the children were labouring under *tabes*, of whom three died; but this is not an unusual circumstance in ships bringing out settlers, in consequence of the change to salt provisions, and the confined air, with crowding in a ship, which must always have a baneful influence upon lactation. Neither the crew nor the cabin passengers were at all affected. The principal symptoms were spongy gums, pains and stiffness of the limbs, loss of appetite, emaciation, with swelling, hardness, and discoloration of the extremities—this latter, however, to no great extent.

It appeared that both the lime juice and suet that had been provided, were of very bad quality, and that no proper stoves for ventilation had been supplied. To these causes the surgeon of the ship attributed the origin of the disease; but I think it is difficult to fix upon any single circumstance as the immediate exciting cause. I do not recollect an instance of the prevalence of scurvy in any other emigrant vessel. The "Australia," which arrived here on 28th February, 1837, bound to the same settlement, of only 155 tons burthen, and which had a

greater proportion of settlers on board, for her size—viz. twelve cabin passengers, and forty-four men, women, and children, in the steerage—had not a single case of scurvy, as far as I am aware. She left Portsmouth on the 22d December, 1836, and must have been exposed to more boisterous and wet weather. She had likewise a passage of seventy days.

It may be essential to mention that most of the steerage passengers of the "Coromandel" were tradesmen brought up in London, with several Germans, but few of the latter became scorbutic; and there can be little doubt, I think, that their former habits, when they came to be deprived of their accustomed comforts on board, contributed much to the formation, extension, and continuance of the disease.

During the year 1836, scurvy was much more prevalent amongst the whaling vessels than it had been for many previous years; which may probably be accounted for from their not having gone as usual to the *westward* to fish, but to the *eastward*; and having got into very high southern latitudes, where they encountered extremely wet and stormy weather: still, however, a difficulty exists to account for the greater prevalence of the disease in some vessels than in others. The American vessel the "Hibernia," a "*temperance ship*," though only out 8 months and a half, came into this port with the crew so disabled from it that they were unable to furl their sails, and obliged to get assistance from the other vessels in the bay: none of the crew, however, died from the disease.

In another vessel, ("the Zephyr,") out three years, all on board were in good health; but this vessel had touched at various places for refreshments during her voyage.

The prevalence of the disease on board the "Hibernia," may be accounted for, I think, from their having been far to the southward, near the islands of St. Paul and Amsterdam; and though she was out only 8 months and a half, yet the crew must have worked very hard; and in addition to the cold they must have been constantly wet. She had a full cargo (2400 barrels of oil), and the labour must have been incessant and the fatigue very great, to have procured so much in that short period. The American captains

fancy that there is something in the water of the southern latitudes that predisposes more to scurvy than that of other climates; it is an opinion they have formed, and of which they appear convinced; but why, I could get no rational theory. I must add that the "Hibernia" had a very great portion of her flour damaged by salt water, the vessel having shipped some heavy seas before it was properly stowed.

The whaling vessels that put into this bay between November 1836 and February 1837, amounted to twenty-seven; all Americans, with the exception of two English and two French; and the period they had been out varied from eight to twenty months and upwards; and all of them were more or less affected with scurvy. The American captains further accounted for the occurrence and prevalence of the disease among many of their crews, from their being composed of raw land youths, many of them taken from the plough, and others who never had been at sea before. Their ships appear to be generally well provided with spruce, treacle, lime-juice, and other antidotes to scurvy; perhaps the best of these is their general success in whaling, notwithstanding that this does not hold good in regard to the Hibernia; for I have seen more than one instance where mental despondency contributed much to induce the disease. I may mention that a great many (indeed most) of the Americans were "*temperance ships*;" but I do not think, generally speaking, that these were more affected than others, although I am of opinion that in cold wet weather, when men are hard worked, an allowance of wine or spirits is often beneficial, and even necessary for the preservation of health.

I am not aware what number of cases were sent to Somerset Hospital, but I believe a very small proportion, and chiefly Frenchmen, and I am unable to speak of the treatment there followed; but the convalescence of the patients, both in the Coromandel and whaling vessels, was very rapid after their arrival here, though few of the passengers of the former were allowed to land. In the Hibernia, where the appearance of the disease was frightful in the extreme, I ordered the diluted muriatic acid, *ad libitum*, and the effect was astonishingly beneficial. I invariably recommended that the men should have a *free range*

on shore, and although the average stay of the ships did not exceed ten or twelve days, all the hands were nearly fit for duty before their departure.

In the scorbutic patients of the *Hibernia*, the gums were so much swollen and spongy that the teeth were scarcely visible; there was great difficulty of breathing, the extremities were thickened and hard, pulse small and rapid, and the prostration of strength such that the poor fellows could not crawl up the hatchway; and yet I saw those men walking about the streets in a few days afterwards.

The crews of the American vessels average about twenty-five or thirty men, and their tonnage is from 280 to 350; they carry no surgeons; but all the French and English vessels have surgeons. I cannot speak positively to the means of treatment used previous to their arrival here; but I believe it consisted of supplies from the cabin table.

Memorandum on Scurvy, by Surgeon Bailey, R. N. Superintendent of the Somerset (Civil) Hospital.

Cape of Good Hope, March 1837.

In the months of January and February last, 22 patients affected with scurvy were admitted into the Colonial Hospital here, from English, French, and American whaling vessels—a circumstance which I do not remember to have occurred at any former period while I have had charge of it, which has been for upwards of eleven years.

In the present day, this disease is rarely met with in ships; but about the end of the last and the beginning of this year, it has prevailed in several whaling vessels, and in two with convicts and settlers, which touched at the Cape on their way from England to New Holland.

Whether in these vessels it originated from any neglect or defect in their domestic economy, or from atmospheric influence, or from any other cause or causes, is a question I am unable to solve satisfactorily; but I have to state that apparently only a few of the whalers in these seas have suffered, although a great many have been fishing in the same places together, and that some of those affected had not been so long out from port as others on board of which the disease has not shewn itself. Only one vessel with convicts, the *Earl Grey*, which arrived in

Simon's Bay after being seventy-one days out from England, and one with settlers, the *Coromandel*, seventy days from England, have had the disease, out of many others of these classes of vessels that touched here; and it has not appeared in any of the common trading vessels, so that I think it cannot be ascribed to atmospheric influence.

I had not an opportunity of seeing the cases, or personally investigating into the cause of the disease on board the convict and settlers' ships; but the men from the whaling vessels attributed their complaints to exposure to cold and wet, without a sufficient allowance of wine or spirits when they were obliged to work very hard under such exposure.

Several of the older hands said they had been much longer out at sea in other whalers without becoming ill, but then they had a more liberal allowance of wine and grog (some said they had also more peas and beans, and now and then molasses); and it is to this they chiefly attributed their exemption on former occasions.

I saw the disease many years ago, in the time of the French war, in some of the prizes which we took; and I then considered it to be owing to the vessels being badly found and regulated, or badly seasoned. I think it is very likely to occur in damp and badly seasoned ships, whether in cold or hot climates.

The crews in the prizes we took consisted chiefly of men who had not been much accustomed to a sea life, and were rather in depressed spirits, as if out of their element, which is a great predisposing cause of scurvy as well as of other diseases; and it is on this account that convict and emigrant ships require to be particularly well regulated.

I believe that if vessels becoming affected with the scurvy be kept out at sea, and cannot come into port to procure fresh meat, fruits, and vegetables, and obtain a cheering change for the sick, the patients will die in great numbers, whatever treatment they may be put under (*i. e.* whether tonic, saline, astringent, or antiphlogistic); but that if fresh fruits and vegetables can be procured in abundance, and if at the same time the vessels be clean, dry, and comfortable, not over-crowded, and well regulated, and the men be kept from desponding, scarcely any other remedies will be required.

I do not, however, by any means

consider it *indifferent* whether the accompanying mode of treatment adopted be tonic, stimulant, astringent, saline, or antiphlogistic.

It is certainly a curious coincidence that the troops stationed on the frontier of this colony, or more properly speaking those in the Caffer province of Adelaide, should have had scurvy prevalent among them at the same time it occurred in the vessels above-mentioned; when, as far as I can learn, this complaint was never known to have prevailed at any former period in that quarter, either among the troops, settlers, or natives.

When the scorbutic cases were admitted into the Somerset Hospital, Dr. Murray, who had been for some time previously studying the nature, causes, and treatment of the disease, in consequence of its having affected the military on shore, came frequently to visit my seafaring patients, and took a great interest in them.

It appeared clearly, from comparing the symptoms, that the disease was precisely the same in both situations; and that sea and land scurvy are therefore identical. It appeared no less evident that scurvy, and what is called purpura hæmorrhagica, are identical, and that purpura simplex is only a milder degree of the same disease. Our comparison of the details of the cases has dispelled the doubts which before existed in our minds, and which still seems to perplex the profession in regard to these points.

At Dr. Murray's request, a comparative trial of different and opposite modes of treatment was carefully instituted in my scorbutic cases, the day after their admission. According to old practice, I had put them all upon full diet, with extra fruit, vegetables, and beer, the first day, and had ordered them decoction of bark with acid; but on the second day, an equal number of them in different stages, and as nearly similar as possible with respect to symptoms, were placed on three different methods of treatment—viz. tonic, antiphlogistic, and saline.

In one set, the tonic plan, as first began, was continued. In a second set, a plan by venesection (if the case was considered to indicate and admit it), antimonials, purgatives (chiefly calomel and salts), refrigerants, diluents, and tepid pediluvia, was adopted, along with very spare diet (no wine, meat, or beer,

but a little soup, with only half a pound of bread; but the same allowance of fruit and vegetables as in set one.) And, in a third set, the treatment was to give a purgative dose (5j.) of Epsom salts in quassia infusion every morning, with diet similar to that in the second set.

The first set had astringent gargles for the mouth, and stimulant embrocations, with flannel rollers to the extremities. The second and third sets had the most simple gargles, and used applications of warm vinegar with flannel rollers to their swelled, rigid, and discoloured extremities.

Three of the second set were bled to 3xvj., 3xij., and 3vij.; in two the bleeding was repeated a second time to 3vij. and 3iv.; and in one it was had recourse to a third time to 3iv., before the pains of the limbs, oppression at the precordia, and difficulty of breathing, were subdued; but the relief and advantage derived from it each time was marked and decided.

As they all had good appetites at the time of admission, the first set were highly delighted with their good allowance of food; but sets second and third were extremely disappointed, and grumbled sadly at the scanty pittance of victuals allotted to them, especially as they thought they required plenty to eat, from being so weakly, and saw their comrades, as they considered, better treated.

To my astonishment, I must say, I found that sets second and third amended in a wonderfully rapid manner, compared with set one, so much so, that in two or three days the worst of them were able to get out of bed and walk about; and, in ten days, nearly all of them were well; while of lot one, only two of the slightest cases were convalescent; one continued stationary, and two of them, in fact, were so much worse, that I was convinced of the expediency of changing the treatment, and adopting antiphlogistic measures for their relief, which proved most efficacious and satisfactory, as their recovery from that time was progressive and steady.

Of set, No. 1, it was found that the cases which were most severe, of longest standing, and most debilitated, were those that did the worst under the tonic and stimulating mode of treatment adopted towards them. They soon lost their appetites, became feverish,

thirsty, and restless at night, their breathing became very much oppressed (a distressing symptom in all chronic cases); the gums continued fungoid, and easily made to bleed; the œdema, contraction, and discoloration of the legs, did not decrease, the pulse became more rapid, the tongue foul, their head ached, their skin became hot and dry, and they continued disinclined, as well as unable, to get out of bed.

The slighter cases were the only ones of this set that recovered, *in reality in spite of the improper treatment.*

I consider the saline treatment employed in set 3d to differ but little from that in set 2d. It happened that we had to bleed one of this set, but only to a small extent (five or six ounces), for the relief of the oppression at the chest. I think, however, that the cases in this set were not quite so severe as those in 1st and 2d.

I published a letter in one of the Cape Town newspapers at the time, giving a brief account of the above-mentioned comparative practice which was instituted, feeling assured that it will afford an instructive hint to my professional brethren, under whatever circumstances scurvy may come under their treatment; and I feel anxious to learn the result of the experience of the military medical officers on the frontier, whose practice has been upon a more extensive scale.

DR. MURRAY'S CONCLUDING REMARKS.—It may appear to some that I have over-extended this paper by repetitions and superfluous details, but I must observe, that what may seem trivial and uninteresting to practitioners in civil life, is often of infinite importance to medical officers.

In requesting the foregoing reports from their respective authors, my object was to obtain as full an elucidation as possible of the source or causes, symptoms, nature, means of prevention, and cure of the disease which prevailed among our troops on the eastern frontier. The investigation has developed some discrepancy of testimony and opinion among them upon certain points, but I trust it will have thrown light upon the subject.

I would wish to impress upon the minds of military and naval medical officers, that to be able to discriminate the first indications or premonitory symptoms of scorbutic diathesis, to un-

derstand its pathology, discover its causes, comprehend their mode of operation, and form just views as to its prevention and cure in various situations, involves a study of paramount importance to their respective services.

Those who have witnessed the effects of scurvy know it to be one of the most insidious and disabling diseases that can attack an army or fleet; and the necessity of medical officers being well acquainted with, and on their guard to prevent it, is the more indispensable as it generally occurs under circumstances when the best means of cure (vegetables and fruits) are unattainable, in which case the best directed efforts of medical skill but too often prove unsuccessful.

The circumstances attending the occurrence of scurvy at the Cape at this time, reminds me of what happened when a disease of a similar nature broke out in the Milbank Penitentiary in 1823, and the most eminent physicians in London were consulted respecting it, upon which occasion considerable ambiguity and contradiction of opinion was found to exist among them in regard to its causes and nature; and indeed a great diversity of opinion still prevails in the profession upon these points. A zealous practitioner, however, will not adopt the opinion of any one without scrupulous examination, but will endeavour, by study and reflection, to obtain a comprehensive knowledge of every disease under his charge, in order to be able to form rational indications of treatment. "Every man," says Gibbon, "who rises above the common level, has received two educations; the first from his teachers, the second from himself;" and as medicine is not one of the exact sciences, no one really anxious for its improvement ought to conceive it a degradation to retract any erroneous opinions or practice he may have formerly advocated.

I have already confessed my former want of discrimination of scurvy, and must also take my share of blame in the want of success which attended the treatment of the cases in the 75th Hospital, at Cape Town. Lately, however, I think I have become better acquainted with it; and since it has been found that the antiplogistic mode of treatment is most conducive to its cure, our former difficulties regarding it have in a great measure vanished, the means of cure are no longer so conjectural and complex,

and no cases of imperfect recovery have presented themselves to those who have adopted it.

The foregoing reports sufficiently point out the absurdity of the numerous divisions which some authors of limited experience or indiscriminating observation have made of this disease. The word "scurvy," in English, sufficiently distinguishes it in all its modifications; and in technical language, the term "scorbutus" (a barbarous Latin word), has been so long in use, that it will probably never give place to any of Greek extraction.

The appellation of "sea or true scurvy," used in contradistinction to the disease which occurs on land, as if the latter were a false species of it, has originated in error, and should be abolished; for there is no more pathological difference between scurvy at sea and scurvy on land, than there is between lues venerea at sea and lues venerea on land*.

The Greek term "porphyra," synonymous with the Latin one, "purpura" (signifying purple or livid disease), is proposed by Dr. Mason Good in lieu of scorbutus, and under this title he includes every description of petechial eruption and spontaneous ecchymosis, not dependent on fever as their cause, considering purpura in all its forms described in medical or surgical miscellanies as appertaining to scurvy, even when not attended with sponginess of the gums, which has been deemed pathognomonic of scorbutus by nosologists; but this name (porphyra) is objectionable, as the disease does not always exhibit purple spots or ecchymosis.

In my prefatory remarks I touched on the subject of the various names which have been given to different (evident) modifications of scurvy by different writers; and I would here further add, that I am of opinion that a great affinity exists between this disease and the affections termed *Pellagra*, *Cachexia Africana*, *Beri-Beri*, *Melana*, *Hæmaturia*, *Hæmatemesis*, *Putrid Dysentery*, and perhaps some others which have got specific and distinct appellations.

* By the way, I consider the modern distinction of venereal into syphilitic and non-syphilitic, to be no less erroneous and absurd. I am often amused in tracing cases returned "Syphilis consecutiva" to primary symptoms described as "Ulcers penis non-syphilitica," and *c. t.* The distinction is generally imaginary, and often leads to error both in science and practice.

PLASTER OF PARIS IN FRACTURES.

BURNS AND SCALDS; TURNBULL ON VERATRIA.

To the Editor of the Medical Gazette.

SIR,

SOMETHING like an apology may be due to your readers for my again addressing you on the subject of treating fractures of the extremities by means of plaster of Paris casts; but when experience gives me renewed and firmer confidence in the excellency of the plan, I feel that I should ill discharge my duty to the community if I withheld from them the results of cases which have, in the course of the last few months, fallen in my way.

Although the employment of the plaster cast is chiefly applicable to fractures of the lower extremities, the subjoined case will shew that it may be adapted in the upper, especially in cases of *fractured olecranon*.

Sarah Matthews, ætät 73, fell and fractured the olecranon of the right arm, which had remained unreduced, at the time she was placed under my care, for three weeks. Apprehensive that, from the long continuance of the separation of the fractured ends of the bone, union would not take place—particularly when the woman's advanced age was taken into consideration, and being sure that, from her impatient temper, no ordinary splint or bandage would secure her—I determined on keeping her in bed, placing the whole arm, from the insertion of the deltoid down to the wrist, in a simple wooden trough, and enveloping it in plaster of Paris, so as to preclude all possibility of motion. At the end of four weeks, I released the arm, and had the satisfaction of finding that union had taken place. The old lady rejoices in the perfect restoration of the use of the limb.

On the 28th of June last, Mr. Read, a respectable farmer, æt. 71, fell, whilst in the act of reaching to unhang a collar from the wall of his stable, whereby he suffered a fracture of the right leg, about four inches above the ankle-joint. I reduced the fracture, and, at the end of a week, when the swelling had somewhat subsided, secured the limb in the plaster cast. The case went on satisfactorily, and at the end of six weeks he was released, a perfect union of the bones having taken place.

My next case was that of a young man, John Perham, who was employed on a public building in this town. A scaffold, upon which he was at work, gave way, and precipitated him to the ground from a height of twenty feet. He fell upon a heap of stones; other stones which were on the scaffold fell upon him. Upon taking him up it was found that the left leg was fractured: the tibia protruded through the integuments and stocking, insomuch that, in order to effect a reduction, it was necessary to remove about an inch and a half of that bone. Both it and the fibula were shattered in an unusually severe degree.

I determined *immediately* after the reduction to place the limb in a double-inclined plane, and envelop it in the plaster, leaving the upper surface of the leg uncovered for the length of eight inches and three in breadth, in order that the wound may be dressed, lotions, &c. applied, as occasion may require.

It was fortunate that I had so determined, because, in consequence of severe bruises inflicted on the body, he could rest only when supported by a bed-chair. At the end of ten weeks the plaster was removed. A perfect union of the bones had taken place, but there is a small wound, through which exfoliations of the bone will most probably be discharged. There is some deformity of the limb, which was inevitable in so severe a case; but, on the whole, the issue has been very favourable.

The cases above reported have been instructive to myself, and interested me in a more than ordinary manner. The evidence of Mr. Read in favour of the method of treating fractures I am advocating is very strong, and such as it rarely falls to the lot of any man to meet with, as he had now suffered a *fracture of the same leg three several times*. The *first* accident was occasioned by his leaping a ditch, about twenty-eight years since: both tibia and fibula were fractured. He was attended by a gentleman in his neighbourhood, who placed him on his back with the limb fully extended, than which no position can be more irksome or painful. Unfortunately for him, the splints were removed too early; the newly-formed bone bent by the weight of the foot, and a permanent curvature of the tibia ensued, which deformed and rendered him a little halt. *Four months after*

this Read fell and fractured the leg a *second* time; was attended by the same gentleman, and treated in the same way. Mr. Read had suffered so very severely in consequence of the position in which he had been placed, that he dreaded the idea of being again placed on the back, not being aware of the difference between the more straight position and the double-inclined plane in which I put the limb. The experience, however, of a few hours convinced him of the superiority of the method now employed, to which he yields a willing testimony; for it may be truly said that, altogether, he had not had twelve hours suffering after the limb had been secured in the plaster.

In Perham's case, which is the first compound fracture I have so treated, I departed from my former route, and at once encased the limb in the cast; and this I think the better plan, where you happen to be called in before any considerable swelling of the limb has come on, because much of the tumefaction and pain is occasioned by the irritation of the soft parts from the broken ends of the bones; and this is obviated by the steady confinement and support afforded by the plaster.

In both these cases, the greatest advantage has been derived from the employment of this material, both from the ease experienced by the patients, and also from the ability given them of altering the position of the body, and of their being shifted from one side of the bed to the other, which is practicable without at all interfering with the curative process going on in the limb, hereby rendered fixed and immoveable. Read was moved daily from side to side, and thus had a new resting place. Perham merely changed his position from a lying to a sitting posture, and *vice versa, ad libitum*.

A short time since I had an opportunity of seeing the model sent by Mr. Beaumont, of Berners' Street, to the College of Surgeons. That gentleman's plan differs greatly from my own, as he first applies an eighteen-tailed bandage round the limb, and places his patient on the side, with the limb in a flexed position.

These differences are, in my opinion, very material. In the first place, one great advantage derived from the plaster cast is the total disuse of all bandages, (which can hardly be applied, even by

the most skilful hand, with entire uniformity of pressure; and this very irregularity occasions much pain to the patient; but the plaster cast supports the limb throughout with a uniformity unequalled by any other means. In the second place, I am inclined to the opinion, that a patient could hardly bear that the limb should rest on the knee and ankle without the interposition of some soft substance. And, again, when a patient lies on the side, it is hardly possible to apply evaporating lotions, which can be very efficiently employed when he is placed on the back.

Mr. Beaumont's contrivance for keeping the limb extended whilst the plaster is being laid on, and retaining it till it is properly set, is ingenious.

I intend shortly to send a model of Perhan's case to the College of Surgeons, in the hope that the attention of some gentleman of mechanical genius may be called to it, and such improvements made in the simple apparatus I have contrived as shall bring it near to perfection. It has been objected, that there must be a difficulty in removing the hardened plaster; but such is not the case, as the material cracks and gives way to a moderate blow from a light hammer and turn-screw or blunt chisel, without the least risk of injuring the patient.—I am, sir,

Your obedient servant,
W. SWEETING.

Bridport, Nov. 12, 1838.

BURNS AND SCALDS.

I have much pleasure in being able to confirm Mr. Greenhow's report of the efficacy of his method of treating burns and scalds, as I have been in the habit of employing it for many years.

TURNBULL ON VERATRIA.

In the last work published by Dr. Turnbull, on the efficacy of veratria in various diseases, and amongst them, on those affecting the eye, the case of Miss Palmer, of Weymouth, is reported as having been cured by this substance. I am concerned to announce the total failure thereof in respect to this lady, who is so blind as to be scarcely able to distinguish light from darkness.

W. S.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abrégé.”—D'ALEMBERT.

Outlines of the principal Diseases of Females. Chiefly for the Use of Students. By FLEETWOOD CHURCHILL, M.D., &c. Dublin, 1838. 8vo. pp. 402.

THIS book does credit to the industry and talents of Dr. Churchill. A work of so much research cannot be perused without profit by any class of students; yet we think it will be read with more advantage by those who have already a considerable knowledge of the subject, than by the mere beginner. The latter would prefer a sketch of this branch of medicine, unclouded by controversial statements; while the former will be glad to find that, under every point which admits of a doubt, the conflicting opinion of French, German, English, and sometimes of Italian writers, are quoted, or referred to. Hence Dr. Churchill's work reminds us a good deal of Cooper's Surgical Dictionary. The following passages are fair samples of our author's manner:—

He observes, that the uterine may be distinguished from vaginal leucorrhœa “by the circumstances in which it is observed, as, for example, after abortion and delivery; preliminary to, and vicarious of, the first menstruation, &c. &c., or by its peculiarities at the menstrual epochs, and its greater effect upon the constitution.” (P. 135.)

Here is a part of his account of the treatment of uterine leucorrhœa:—

“There is no more striking distinction between the two species of leucorrhœa, than is to be found in the effects of astringent injections. In vaginal leucorrhœa they are extremely successful, the symptoms are ameliorated, and the discharge arrested without any unpleasant consequences. This is not the case in uterine leucorrhœa: if no evil results from their employment, the patient derives no benefit, but continues to labour under the discharge for months together*. In other cases, I have known

* The substance of this chapter was published in the Edinburgh Journal, No. 121, and since that I have received several gratifying communications from professional gentlemen in this country and in England, as to the success of the plan of treatment I ventured to recommend. They have all especially instanced its efficacy in cases

them to cause great irritation, with menorrhagia and an aggravation of the local distress.

"In cases of the *acute form* of uterine leucorrhœa, it will generally be advisable to commence by cupping the loins or applying leeches to the vulva. After this, hip-baths and vaginal injections of warm water (a uterine warm bath) may be employed until the acuteness of the attack has subsided, and the patient is in a condition favourable to the application of counter-irritation.

"At this stage in the *acute*, and at any period in the *chronic* form, a blister may be applied to the sacrum, and repeated once or twice, if necessary. Its effect, in most instances, is an immediate diminution of the discharge, and a mitigation of the local uneasiness.

"There are four medicines from which I have seen benefit derived.

"1. Balsam of copaiba, given in increasing doses, commencing with 15 drops three times a day; or, if the stomach be delicate, it may be made up into pills.

"2. Preparations of iron, and especially the sulphate. The mode in which I have exhibited it is in combination with blue pill, and the compound rhubarb pill. It improves the condition of the digestive system, and appears to exert a decided influence over the leucorrhœa.

"3. Decoction of logwood. In two or three cases in which I made trial of this medicine, it seemed to be very useful; the discharge diminished, and the patients were ultimately cured.

"4. Ergot of rye. This remedy has been highly recommended by MM. Roche, Dufrenoy, Bocquet, Negri, Ryan, &c., and, in some very obstinate cases in which I prescribed it, it succeeded after the failure of other medicines*. I gave it in doses of five grains three or four times a day.

"These are the remedies which I have found the most efficacious, but their effect is greatly increased by the previous application of the blister.

"There are other medicinal substances which have their advocates; powdered colchicum root was recom-

mended in a recent number of the American Journal of Medical Sciences, but it failed in my hands.

"Iodine has been highly praised for its effects in leucorrhœa. MM. Brera, Gimelle, and Sablairolles, are said to have used it successfully in old and obstinate cases*. Gimelle gives an ounce of the syrup of iodine, evening and morning, in some appropriate infusion†.

"Nauche speaks well of aromatic medicines. My friend Dr. Hunt informs me, that he has succeeded in curing leucorrhœa by capsicum alone, in doses of two grains three times a-day.

"In some cases it will be advisable to prescribe some vegetable tonic, as the sulphate of quinine, along with these special remedies."

It is to be hoped that the destructive operation of cutting out the neck of the uterus will not again be attempted in this country. Dr. Churchill says he is not aware that the attempt has been made; but we believe that it has been made more than once.

The following passage may aid in preventing a repetition of these trials:—

"I. *Excision of the neck of the uterus*.—This is an operation which has been performed repeatedly on the continent, though but rarely in this country; and opinions as to its propriety and safety have varied very much.

"Osiander excised the cervix, with more or less of the body of the womb, nine times with success‡, the subsequent hæmorrhage being easily restrained.

"M. Dupuytren§ performed the operation fifteen or twenty times, with success.

"M. Hervez de Chegoïn also operated successfully in one case related by M. Duparcque.

"But the great advocate for this operation (the *apostle* of excision, as Dr. Balbirnie would call him) is M. Lisfranc. On his evidence, professional men were almost persuaded that it was as simple and safe as his cases were numerous. It has been shewn, however, by M. Pauly||, that his operations

* See art. Iode, by M. Solon, in *Nouv. Dict. de Méd. et Chir.*

† See cases in *Journal Univ. des Sciences Méd.* tom. 25, p. 5.

‡ For a succinct account of Osiander's views see *Edinburgh Med. and Surg. Journal*, vol. xii. p. 285.

§ Duparcque, *Traité des Altérations*, &c. p. 437. *Journal Gén. de Méd.* vol. cix. p. 214.

|| I. Instead of the 99 operations stated by M.

where injections had failed. I can truly add, that my own confidence in it keeps pace with my increased experience."

* See Lisfranc, p. 379—note by M. Pauly."

were fewer in number than was asserted; and that so far from being either safe or successful, several died within twenty-four hours after the operation, and a considerable proportion (more than two-thirds) were ultimately lost.

"In consequence of this discovery the operation is now regarded with great suspicion."

A remarkable case is given in the note, at p. 284-5, of a woman who bore a child, though she had an irreducible *prolapsus uteri*; and curiously enough, after giving the history of the case from Nauche, our author immediately gives it again from Capuron, and calls it "a similar case."

If the plan of the present volume is approved of, Dr. Churchill means to publish another one containing the diseases of women which occur during pregnancy and child-bed. We wish all possible success, both to the forthcoming work and to the one which is now before us.

MEDICAL GAZETTE.

Saturday, December 8, 1838.

"Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

CASES OF MALAPRAXIS.

In our last article on this subject (November 10), we gave three cases of

Lisfranc to have been performed by him, only 53 can be made out.

"2. There are no exact accounts of the failures which happened in hospital.

"3. Out of nineteen private patients operated upon, only one has been permanently benefited.

"4. Of these nineteen cases, four died within twenty-four hours, twelve had an immediate relapse, and in two others, the carcinoma not being entirely removed, the patients only sank the more rapidly.

"5. Out of nine patients operated upon under M. Pault's observation, and near whom he remained twenty-four hours, six were attacked with frightful hæmorrhages; and of these six, three died within twenty-four hours.

"In addition, abundant proof is afforded, that in many cases excision was utterly uncalled for by the nature of the disease (p. 476). Such facts are enough to deter the most hardy from attempting this fearful operation; and the exposure of such mis-statements is a striking lesson to all who, in order to make a reputation, are ready to forsake the paths of honour and truth.—Lisfranc, *Mal. de l'Uterus*, p. 427, *et seq.*"

malapraxia occurring in Germany, together with the judgments of the medical tribunals to which they were submitted. In all these instances the accused may be considered as having been found guilty, and punished; for although a punishment *eo nomine* was inflicted only once—although Dr. X. alone was fined, yet the reproof bestowed upon the midwife and the surgeon, in the other two cases, must be deemed to be pretty severe punishments. In a profession like ours, where reputation is subsistence, whatever sullies the one destroys the other: "a breath has made them," and a breath can unmake them.

In the cases we are about to detail from the same respectable source, the practitioners are equally unfortunate; and one of them, as our readers will see, more culpable, or more severely visited than his fellow-criminals, is actually struck off the list of surgeons; yet, in spite of his legal non-existence, he continues to *malpractise*! So difficult is it to put such laws in force, even in despotic states; what, then, could be expected from the inquisitorial regulations which some medical reformers would wish to inflict upon this country?

Let us now proceed to consider a few more of the instances accumulated by Dr. C. F. Koch for our instruction; the first being an inquiry into the conduct of a midwife:—

Mrs. P. had borne children seven times safely and easily; she was now pregnant for the eighth time, when, on the evening of the 5th of February, the waters came away unexpectedly. S., the midwife, was sent for, but during the first hours of her attendance she did not make an examination; (this, however, she denied.) After midnight the midwife wished to fetch an accoucheur, but the woman and her husband refused to

allow it. In the morning, however, the mother-in-law came in, and insisted on having an accoucheur sent for. Accordingly the midwife called upon one, to inquire if his presence was necessary. The accused stated that she had immediately examined the woman, and found that the os uteri was open to the size of a half-crown, and that the elbow presented; but that she wished to satisfy herself more perfectly of the position before she called in an accoucheur. About ten o'clock she found that it was an arm presentation, and told them that she could not complete the delivery herself; but the woman and her husband would not hear a word of it. Meantime several hours passed away without pains, during which the woman occasionally slept.

Mr. M., a surgeon, deposed that the midwife came to consult him, and that he went with her directly. The woman did not allow him to examine till after being repeatedly persuaded by the husband; and he then found the right arm presenting, and the shoulder wedged in the pelvis. He introduced his hand, caught hold of the feet, and brought them down to the entrance of the pelvis. The powerful contraction of the uterus now paralysed his arm, so that he was obliged to ask for the assistance of another accoucheur. This he obtained in the person of Mr. H., a *Kreis-Chirurg*, or distinct surgeon; a man, therefore, of superior professional rank to an ordinary practitioner. With his assistance a dead child, at the full time, was brought into the world, the two surgeons relieving each other from time to time. The woman screamed violently, and lost much blood. The cause of death appears to have been inflammation of the uterus.

Mr. H. deposed that he found the woman very hot and thirsty. The right shoulder of the child was wedged in. He first injected milk and oil, and then

introducing his hand, he brought down the feet with great exertion, because it was only with great exertion that the shoulder could be removed from the entrance of the pelvis. The patient lost blood, but this was not the cause of death: she sank under inflammation of the uterus and peritoneum. An emulsion was prescribed, of poppy-seeds, with nitre and a few grains of extract of hyoseyamus; injections of resolvent herbs with hyoseyamus; and frictions with volatile liniment and tincture of opium. Mr. H. afterwards ordered ten or twelve leeches to be applied to the abdomen. In the evening the pulse was much quickened, and there was great restlessness; and so it was on the next morning, when he saw the patient for the last time.

The board give rather a long opinion on the merits of this case. In the first place they observe, that the questions whether the midwife shewed herself so ignorant as to be unworthy of the exercise of her art, and whether she was guilty of the death of the mother and child, are to be separated from each other. As to the first question, they pleasantly remark, that *if* it were proposed to them, they should undoubtedly say "Yes!"—but they are unable to give a decided answer to the second one for want of facts.

As to the child, they say, we hear nothing more of it than that it was born at the full time, large and dead. It does not seem that the accoucheurs made any attempts at resuscitation, and it may therefore be supposed that they thought it had been long dead; yet they do not back this opinion by any argument.

The midwife alone declared that the child was living when Mr. M. came in, but without giving any grounds for this supposition. In any case, turning is so dangerous an operation for the child, that one in three, on the average, is sacri-

fieced by it. The attempts, however, of the accoucheurs to deliver the woman do not seem above censure. Mr. M. confesses that he introduced his hand into the uterus to turn the child, before he had tried to push back the presenting shoulder, and dilate the uterus; indeed, he pulled at the child's feet, though he was of opinion that the shoulder was still wedged in the pelvis, under which circumstances he could hardly introduce his hand into the uterus. Mr. H. attempted delivery in the same way, and succeeded; but we are not informed how it was accomplished by the *alternate* efforts of the two surgeons.

Hence it appears—first, that it has not been made out that the child was alive till the time of birth; secondly, that it is doubtful whether the child came into the world dead, or only apparently so; thirdly, that it cannot be decided whether the child's death was caused by the accoucheur's method of proceeding or not; and lastly, as turning is a most dangerous operation for the child, even under the most favourable circumstances, it cannot be decided whether the midwife caused the death of the child by her negligence. As to the woman's death, it appears that she had considerable hæmorrhage after delivery (the separation of the placenta is not mentioned); that she complained of violent pain in the abdomen, with heat and a quick pulse; that she was restless, and had no sleep; that on the following morning she suffered from hiccup and vomiting; and that she occasionally wandered in her mind, with great depression of strength, till death closed the scene.

The Board thought it very probable that the patient died of inflammation of the uterus, as the accoucheurs supposed; but that the midwife might retort their accusation, namely, that she had injured the genital parts of the patient by undue violence, and had *alone* caused her death.

It must be confessed that all the parties in this case are roughly handled; and as we once before observed on a similar occasion, unless midwifery is conducted in Germany with a perfection quite unknown to this country, this must be considered an example of exceptional justice, where a few are picked out for censure, and multitudes err unreproved.

In the next three instances, a surgeon, named S—, was the criminal.

G. broke his thigh-bone by a fall from a carriage; Mr. S. being called in, used extension by the pulley, fastening the rope to the patient's foot, and to the lock of a door which opened inwards; but neglected to shut the door. On drawing the rope, the door flew open, and caused the patient violent pain. The surgeon then put on a wooden splint, reaching from the hip to the heel, and fastened the foot to two iron half-loops, in such a fashion that the fragments of the os femoris were pushed far over each other. The fracture was a compound one. The surgeon treated his patient only six weeks, during which time his condition became so bad, that when cured, his thigh was quite deformed.

The Board acknowledged that fractures of this kind take long in healing, and are apt to leave deformities behind; but on the other hand, they declared the incautious application of the pulley, and the putting up the thigh in such a way that the fragments of bone overlapped each other, to be proofs of ignorance and gross carelessness.

In the next case, the same surgeon was called in to treat the child of a mechanic, aged fifteen months; it had been restless for several days, cried a great deal, and was suffering from diarrhœa, and pain on pressure of the abdomen. He prescribed a mixture of the tinctures of opium and cinnamon, in the proportion of one part of the former to three of the latter, of which

six drops were to be taken every hour. Immediately afterwards the child fell into a state of sopor, with swelled abdomen, laborious respiration, and a small, trembling pulse. The child lived for several days under the treatment of Dr. X., which was by no means perfect.

The Board decided, that although the return of the child's disease was very doubtful, still the prescription of the accused could only have proceeded from unskilfulness.

It is difficult for us to give an opinion upon this case, as we do not know the strength of the tincture of opium prescribed. If we recollect rightly, in the Saxon Pharmacopœia, there is a Tr. Opii three times the strength of the London one. But let us suppose the tincture to have been of the same strength as ours. The patient took a drop and a half every hour, which would be a dangerous dose if often repeated. It would seem, however, that the child fell into the state of sopor, after a dose or two, if we understand the phrase "immediately afterwards." Could this be a case of poisoning by opium? According to Christison, the ordinary duration of a fatal case of poisoning by opium, is from seven to twelve hours, the extremes being three and twenty-four; but this child survived several days. We do not know whether these two unlucky cases gave the *coup-de-grâce* to the professional existence of surgeon S.; but in the title of the next one we found it stated that he had, in the mean time, been removed from practice.

In the last instance this unskilful practitioner was called in by a midwife to a woman in labour with a preternatural presentation, the funis having prolapsed. The case is interesting, but too long to give in detail. Let it suffice to say, that he cut off the child's arm, and left a crotchet sticking in the woman, while he sat down to supper.

A pain came on, and a dead child and the crotchet were expelled at once. The woman died on the eleventh day after delivery, apparently of puerperal fever. The Board censure the surgeon's obstetrical and malapraxia as being beyond, or, as we say, beneath all criticism; nor does the midwife escape unscathed; she knew, say the Board, that the funis presented at noon, but did not send for further assistance till night.

In considering these cases, together with those which we have laid before our readers four weeks ago, there are two obvious conclusions to be drawn from them. The first is, the preponderance of obstetrical cases. Out of seven instances of malapraxia, four are purely obstetrical. Considering how small must be the number of obstetrical cases requiring manual assistance compared to the whole number of surgical operations, this seems singular. Perhaps, because the majority of labours are so easy, some practitioners are unprepared for any difficulty; and in Germany the number of bad cases must be increased, by the custom of employing ignorant midwives in the first instance.

The other conclusion is, that in the practice of the healing art, inattention brings a man into more scrapes even than ignorance. The case of Mrs. S., the patient who laboured under hepatitis, is a glaring instance of the effect produced by prescribing for a case without seeing it; and in the case of the eminently unskilful surgeon S., his coolly sitting down to supper while the crotchet was sticking in his patient, and his omitting to see her after her confinement, no doubt contributed more to his disgrace than the ignorance of the elements of midwifery, with which he is reproached by the Board. Nor is this unjust; for independently of the cases lost by negligence, the feelings

of the patients must be deeply wounded, when the indifference of the practitioner is but too obvious; and if the object of the healing art is to relieve pain, such conduct is a gross infraction of its rules.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

November 27, 1838.

Memoir on Tophlo-Enteritis, or Inflammation and Perforative Ulceration of the Cæcum and Appendix Vermiformis. By JOHN BURNE, M.D., Physician to the Westminster Hospital.

THE author of this paper laid a memoir on the same subject before the Society, in May 1836 (vide Med. Chir. Trans., vol. xx.), to which latter the present might be considered a supplement. The author commenced his second memoir by some observations, anatomical and physiological, on the causes of the comparatively pretty frequent occurrence of tophlo-enteritis. He was of opinion that the ordinary result of spontaneous inflammation of the cæcum was resolution, but that perforation of the intestine was a consequence to be looked for in most cases, in which the inflammation depended on the presence of an irritating substance, impacted in the appendix. The cure of tophlo-enteritis by resolution was then illustrated by particulars of three cases; the author insisting strongly on the use of mercurials and saline aperients, as the best remedies in addition to local blood-letting. The history of perforative disease of the appendix especially, was then entered on. The author first pointed out the great variety of local relation for which the appendix was remarkable, the organ varying much in its place of origin, in its length, in its position, and presenting in consequence, much and embarrassing variety in its apparent seat and symptoms. Four cases were then given of tophlo-enteritis, arising from perforation of the appendix; of which three were verified by dissection. The author next made some remarks on the diagnosis between spontaneous tophlo-enteritis and that occasioned by disease in the appendix; in which he held that in the former, when the bowels were relieved, amendment usually followed; whereas, in the tophlo enteritis from diseased appendix vermiformis, no such benefit could be expected to follow purgation without the removal of the irritating substance. After detailing a case of fatal tophlo-enteritis of the latter kind, the author made

some observations on the literary history of the disease. He, in the first place, stated that he had in his former paper omitted, inadvertently, to make due acknowledgments to Dr. Copland, as an author who had, in his Dictionary, given "extensive information on the diseases of the cæcum;" and then proceeded to criticise the statements and opinions of several other previous writers, foreign and domestic, with a view to shew that they had misapprehended the facts they had observed—viz., Dupuytren, Husson, Dance, Menière, Ponceau, and Louyer Villermay, in France; and Mr. Ferrol, in Ireland. The author then stated summarily his own views as to the causation of tophlo-enteritis, viz.—1. Fæcal accumulations in the cæcum; 2. Presence of worms, concretions, &c.; 3. Previous chronic disease of cæcum; 4. Perforation of cæcum or appendix. The author then made some further observations on the diagnosis of tophlo-enteritis in general, and on its varieties in particular, and concluded his paper by a numerical analysis of twenty-one cases of tophlo-enteritis that had fallen under his own observation. Of these, eight died; nineteen were acute; eleven were simple inflammations of the cæcum, and all recovered. Two were chronic disease of the cæcum, and both fatal; six were instances of perforation of the appendix, of which five were fatal. One was perforation of the cæcum from within—recovered; and one was inflammation of appendix, with peritonitis—fatal. Sixteen were males; two were under 10, and three over 50, and the rest distributed over the intervening years. Six were gentlemen; the others of the labouring class. Most occurred in autumn and beginning of winter.

WESTMINSTER MEDICAL SOCIETY.

Saturday, 24th November, 1838.

MR. F. HALE THOMSON, PRESIDENT.

New Mechanical Apparatus of Mr. John Read, —Poisoning with Carbonic Acid Gas.—Dr. Reid on the Signs of Pregnancy.

MR. JOHN READ, the well-known and ingenious patentee of the stomach pump, was introduced to the Society by Dr. J. Johnson, for the purpose of explaining the construction and use of an apparatus which he had invented for withdrawing atmospheric pressure from any portion of the surface of the body. The machine exhibited by Mr. Read consists of a large glass cylinder, into which the entire arm

may be introduced, and fixed by a copper, or gum elastic, or leather band, which embraces the limb so closely as to hermetically seal the tube. At the closed end of the cylinder is a stopcock, which communicates with a flexible tube proceeding to the pump, which is employed in exhausting the air in contact with the surface of the confined limb. The valves employed by Mr. Read in this air pump are exactly the same as those of the common stomach pump.

Mr. Thomson, the president, placed the machine on Mr. Read's bare arm, and moved the piston two or three times. The circulation of the limb was soon visibly impeded, and a moisture was perceptible on the inner surface of the glass. Two more movements of the piston made the vacuum so painful to Mr. Read, that he cried out for relief.

Mr. Read's invention is an improvement upon the pneumatic apparatus of M. Junod, by whom the cylinders are made either of glass or of copper, and of various sizes, so as to include an arm, a leg, or half the body, as may be desired. This machine is now extensively employed in France as a therapeutic agent, acting upon the old principle of *derivation*. It has been employed successfully in apoplexy, hemiplegia, amenorrhœa, palpitation of the heart, and (by producing a temporary collapse) in reducing difficult dislocations. M. Junod's apparatus consists of three chambers. Besides the cylinder and the syringe, there is a small intermediate chamber, to which a barometer is attached, for the purpose of measuring the degree of vacuum to be produced. This appears, however, to be a piece of supererogatory refinement, for the sensations of the patient are a sufficient index of the pressure for the guidance of the practitioner. The intermediate chamber of Junod, called the *receiver*, is a transverse cylinder of copper; four stop-cocks are attached to it, and communicate with the various cylinders. The valves of the pump of Junod are very inferior to those of Read, being springs (like the keys of a flute), and therefore very liable to get out of order. Read's valves being simple globes, may last for twenty years.

Some discussion has recently been excited touching the merit of the invention. Sir James Murray and M. Junod both claim originality, but it really appears that the principle is pretty nearly as old as Methuselah. Mons. Dionis, more than a century ago, writes on dry cupping; and in the beginning of the present century Dr. Ralph Blegborough published a paper, in which he entirely anticipates the present inventors.

Mr. Read's apparatus has the merit of

economy, for the pump may be used as well for a stomach or rectum syringe, or may be employed to inject air into the lungs of asphyxiated persons. In order to prove its powers in this last respect, Dr. Kingston passed a short tube, terminated by a hilt, into the fauces of Mr. Read, who had previously, as far as possible, emptied his lungs by a powerful expiration. The hilt, already named, hermetically seals the mouth, and the nostrils are to be closed by an assistant, who, after three strokes of the piston, is to relax his pressure upon the nares, that the air may escape. By this means an artificial respiration is kept up, and if there is any vitality left in the patient, every chance of re-igniting it is afforded.

In reply to a question from the President, Mr. Read stated that the expenses of a box of apparatus answering all these purposes, was 4*l.* 10*s.*

After the retirement of Mr. Read, Dr. Chowne inquired of Dr. Golding Bird if the evidence ascribed to him by a report in the *Times* of that day, and referring to a case of supposed poisoning by carbonic acid, was correct. In the *Times*, Dr. Bird was made to say that *twelve* per cent. of carbonic acid diffused in the air, was sufficient to produce death; but that *ten* per cent. was not. He (Dr. Chowne) would be glad to know of Dr. Bird whether he really thought that the *two* per cent. constituted the difference between life and death?

Dr. Bird replied, that the evidence ascribed to him by the reporter in the *Times*, was not only not correct, but the precise contrary of what he said. It was not to be supposed that he could state that 10 per cent. of carbonic acid could be inhaled with impunity, when he knew that 8 per cent. was sufficient to produce a spasmodic closure of the glottis. What he really stated in evidence was, that different quantities of carbonic acid produced different effects; four per cent. would produce coma, a little more asphyxia, and from 8 to 10 per cent. suffocation, by spasmodic closure of the glottis. With regard to the man who died in St. Michael's church, in the city, a difference of opinion existed. Mr. Cooper, the eminent chemist, thought that the carbonic acid, when generated, would be rendered specifically lighter by the augmented carbonic, and consequently ascend to the top of the chamber; whence, as it cooled, it would gradually descend, and mix in wholesome proportion with the atmosphere, thus proving totally innocuous. In his (Dr. Bird's) opinion, this law of the admixture of gases was not proved. In all crowded assemblies, in all ventilated apartments, in the *Grotto del Cane*, and in the celebrated

Valley of Death in Java, it was shewn that carbonic acid had no great disposition to intermix with other gases, but remained in dense strata near the ground. In St. Michael's church, near the stone where the man lay dead, the air over the floor was highly impregnated with carbonic acid. In stooping to collect some of it in a phial, he (Dr. B.) was affected with headache and throbbing of the temples; and some water, which he held in his hand, was *instantly* made turbid.

The heat emanating from the stove was never higher than 68° Fahr., and therefore not sufficient to cause, as had been stated, an unwholesome exhalation from the adjacent tombs.

His (Dr. B.'s) observations were not directed against Harper and Joyce's stove in particular—this was certainly a most elegant contrivance—but against all such apparatus in which no sufficient vent was given to the gases generated by the combustion of charcoal.

This subject exciting a good deal of interest, Dr. Reid, by whom a paper was announced to be read this evening, "On the Signs of Pregnancy," offered to postpone his paper till another evening, if such were the pleasure of the society. This proposal, however, was overruled by the President, who directed Dr. Reid to proceed according to the regular course of the business of the night.

Dr. Reid accordingly read a very succinct and perspicuous essay on the signs of pregnancy. The greater part of the evening being exhausted in the previous discussion, he omitted a great part of the detail of the subject: he passed over altogether the general signs of pregnancy, and considered *seriatim* the individual signs. As regarded each of these, he quoted the opinions of all the most eminent obstetric writers that have written within the last century, either in this island or on the continent. He compared their several statements, together with his own experience, and the conclusion to which he arrived was, that no one sign could be considered *certain*, but that a collection of these signs might afford the highest possible moral certainty.

The enlargement of the mammae, though general, is not universally present in pregnancy. The existence of a brown areola round the nipple, though common, yet is occasionally wanting in the pregnant woman, and sometimes present in the virgin. The projection of the mamillary follicles is equally uncertain, and the same ambiguity may be predicated of the mucous serosity which occasionally covers the nipple. Dr. Hamilton, of Edinburgh, however, places a high value on these symptoms. Sickness may be produced by

enlargement of the womb from any cause, and may be altogether absent. The catamenia do not cease in some women after conception. The enlargement of the abdomen, and even of the womb, may occur without pregnancy; so may also, consequently, the prominence of the navel. The occurrence of what is called quickening is a very delusive circumstance, and may exist purely in the imagination of the patient. Even the motions of the child may be imagined, and may consist merely of contractile movements in the parietes of the womb. The examination per vaginam may perhaps afford the best criterion; but it is difficult to deduce a correct law as to the state of the os tincæ. M. Velpeau states that in pregnancy the vagina invariably presents a violet or purple colour. Dr. Reid has not much faith in the French mode called the "*bullotement*." Even the presence of the hymen is not inconsistent with pregnancy, as was evident in the case related on the previous Saturday by Mr. Streeter.

The stethoscope, or even the application of the naked ear, afforded good means of diagnosis in the latter months of pregnancy. The fœtal pulse can by this means be distinctly counted; but occasionally, from a change of position of the child, the sound of the pulsation is lost for some time, and after an interval again becomes audible. The *bruit de soufflet placentaire* is sometimes present in the cases where any tumor compresses the large arteries of the abdomen, and therefore cannot be considered a safe criterion. The application of an acoustic tube to the os uteri would be nearly impracticable in this country, from the refined delicacy of our women.

The discussion of this important subject was, by general consent, postponed to next Saturday evening.

DIOS.

REPORT ON WEATHER AND DISEASE AT HAMBURGH, IN 1837.

[Concluded from p. 810.]

Fourth epidemic: the Measles.—Single cases of measles began to appear in August, and were epidemically diffused about the middle of October. The epidemic first broke out in the higher part of the new town, which lies towards the north-west, then spread over the whole town, and reached its acmé towards the end of the year.

The first cases were of a mild sort, so that in October there were only two deaths, from measles, while the number in November was 23, in December 61, in

January (1838) 48, and in February and March 16 each. The precursory symptoms were of a gastric character, and it was rare that the eruption was preceded by pains in the limbs, or bleeding from the nose. The eruption was regular, was generally very thick, and remained visible a long time; the attendant fever was commonly very moderate. The cold in the head, and the affection of the eyes, were also slight; the cough, indeed, was mostly dry for some days, but was rarely accompanied by any important degree of oppression, but much more frequently by a vomiting, which very much relieved the patient. Diarrhoea was a frequent occurrence, and from its violence occasionally a dangerous one; in December, however, it was rarer, and gave place to the complication with thoracic inflammation, which not unfrequently gave rise to hepatisation of the lungs, as appeared in dissection. Bronchitis was a rarer complication in proportion, in this epidemic, as were also sore throat and croup. Otorrhoea and transient deafness were common.

The activity of the skin varied extremely: in the beginning of the epidemic the patients were often, as it were, bathed in perspiration, which, at a later period, was more rarely remarked: the desquamation was seldom considerable. In a few cases the little patients were seen suffering under regular asthmatic attacks; and towards the end of November, and in December, several cases of measles occurred, which must be designated as altogether nervous or asthenic. The eruption was mostly of a livid colour, the pulse quick and small, the sensorium dull, and a sense of oppression was present; there were no evacuations; the tongue was dark brown, with fissures, or else red and smooth. In such cases warm baths, with cold effusion, occasionally did good, but the majority died about the third or fourth day. The reporter in one week lost three children, of the ages of four, five, and six, belonging to a very indigent family, in one sick room, by measles of this kind. Adults, too, were not spared by this epidemic, and sometimes died by metastasis to the nobler internal organs; but this was more the case in the first months of the year 1838, for among 86 deaths by measles up to the conclusion of 1837, there was only one person more than ten years old; while among 80 deaths by measles in the first three months of 1838, there were three adults. Excepting these cases, the children who fell victims to the epidemic were chiefly either those who were cutting their teeth at the same time, and sank under convulsions during the time of the eruption, or else those who were already in a state of atro-

phy, or had a deformed chest (*pectus carinatum*), &c.

On the whole, the epidemic must be looked upon as of a favourable kind, as the number of deaths bears a very small proportion to the great number of cases, the epidemic having spared but few houses. It was interesting to see the measles in several cases immediately followed by chicken-pox, which was generally thick. In a very few cases these exanthemata ran their course together, which did not make the patient's condition worse.

In the beginning of the epidemic diarrhoea was frequently an after-disease, and sometimes proved fatal by exhaustion. Another sequela was stomacace with aphthæ, in many cases where not a grain of calomel had been taken. At a later period the more frequent sequelæ were the numerous host of scrofulous affections, chronic cough, incipient phthisis, and the like.

And now for a few words on the other diseases of the year. It is obvious from what we have already said of the *genius epidemicus* of 1837, that catarrhal maladies were the most frequent. Besides the influenza colds were very common in March; in April catarrhal fevers were very frequent among children, and often so intense that local blood-letting was necessary. These fevers often terminated in a branny desquamation, and sometimes during their first days were attended with an eruption like that of scarlatina. The cough was often spasmodic, and the sputa sometimes bloody. In adults, in whom they were upon the whole milder, they were sometimes complicated with angina, and the larynx was pretty often affected. The crisis generally came on with perspiration. In May, under the mask of catarrh, inflammation of the chest was often concealed in children, which even at a tender age required venesection, but in many cases terminated fatally, chiefly from the diagnosis being too late; in older persons the catarrhal fever sometimes changed into a nervous one. From this time catarrhal diseases were rarer, until after the middle of October, when they reappeared in greater number, and with increased intensity, particularly among children, and accompanied the year to its conclusion.

Rheumatism did not always appear as a mere complication of catarrhal maladies; several times, too, those cases were seen, which have been observed for some years, where the rheumatism, which had appeared fixed in one or other extremity, suddenly transfers itself to the heart or brain; and then, neither checked by abstraction of blood, nor by counter-irritation, nor by any other remedy, soon destroys the patient--circumstances which

more frequently occur among the higher classes. The Bills give nine deaths from rheumatic fever, and eleven from acute rheumatism. In children the extremities were often seen stiffened and inflexible from rheumatism. Rheumatic inflammations of the eyes and ears, angina, lumbago, toothache, and even rheumatic paralysis, were frequent.

Gastric diseases were frequent only about the time of the cholera, with the exception of the dyspeptic affections to which the higher classes are subject yearly towards the end of their winter feasting. Jaundice, in particular, was seldom observed this year; diarrhœa, stomacace, and aphthæ, were the most frequent, the last being occasionally combined with the symptoms of nervous fever. Among inflammatory diseases the number of pleuro-pneumoniae alone were considerable; 310 persons died by this disease, of whom 124 had not yet reached their tenth year. Inflammation of the brain was rare; 44 cases were fatal. Hydrocephalus is given as the cause of death 188 times; *gastromalacia* (softening of the stomach), 24 times; croup, 47 times.

Nervous diseases were not very rare. Convulsions proved fatal to 353 children, and one woman. *Trismus neonatorum* was fatal in 36 cases. There were 18 deaths by *asthma thymicum*, 1 by *asthma Millari*, 14 by asthma, 21 by epilepsy, and 22 by delirium tremens. The number of fatal cases of nervous fever was 154, of which, however, only 17 had the typhous character, the majority appearing originally as gastric or gastro-venous fevers.

Diseases of the vascular system were, on the whole, not frequent. The large number of deaths from apoplexy (of whom 349 are put down to sanguineous, and 145 to nervous apoplexy), arises chiefly from the epidemic influenza having destroyed old people in this manner. *Hæmoptysis*, *hæmatemesis*, and hæmorrhage from the uterus, carried off 36 persons, and *morbus petechialis* was fatal to 4. Bloody diarrhœa was observed especially in children, sometimes accompanied by tenesmus, and not seeming to be connected with dentition.

As to chronic diseases, it is evident from the account of the influenza that the number of chronic diseases of the chest must have been very considerable, and therefore 972 deaths by phthisis will not appear surprising. Dropsies were common, and proved fatal 300 times. Lastly, gout, epilepsy, and the most varied forms of serofulous cachexia, were not rare.

Eruptions accompanied by fever were very rare, with the exception of measles and chicken-pox of the most favourable kind. Small-pox occasioned only nine deaths, which is much below the yearly

average at Hamburgh. Scarlatina, which scarcely appeared but in the first half of the year, and then only sporadically, is mentioned as the cause of death five times. *Urticaria* and *Zoster* appeared occasionally. In our account of the influenza we have already spoken of *Herpes labialis*, and of erysipelas. The latter proved fatal 16 times, besides a case of *Erysipelas neonatorum*.

Eruptions unaccompanied by fever were likewise not very frequent.

Whooping-cough and agues were seldom seen.

[Slightly abridged from a paper by D. R. Warburg, in the *Zeitschrift für die gesammte Medicin*, for September 1838. Besides his own observations, Dr. Warburg had access to those of the Medical Society, and to those of the Dispensary physicians (*Armenærzte*), who treated 14,297 cases, so that his deductions are drawn from a large collection of facts. The fewness of the deaths from small-pox—only 9 in a population of 130,000—is worthy of note.—TRANSLATOR.]

LECTURES

ON THE

CHEMICAL HISTORY, PATHOLOGY, AND
MEDICAL TREATMENT

OF

CALCULUS,

AND THE VARIOUS DISORDERS OF THE

URINARY SYSTEM.

By DR. VENABLES.

GENTLEMEN,—We now come to a class or order of diseases of the greatest importance, whether considered in relation to the character and reputation of the practitioner, or the health and comfort of the patient. As relates to the patient, there are perhaps no diseases which inflict greater suffering, more speedily break down the health, and finally lead to a fatal termination. As relates to the practitioner, it should be his duty to qualify himself, by diligent study, for investigating and determining the nature of these diseases. This I state, because the mode of inquiry in cases of the description under consideration differs materially from that ordinarily practised in the generality of other disorders. In most of the disorders which afflict the human body, the attention of the practitioner is exclusively directed to those disturbances which manifest themselves in the general operations of the economy. Those disturbances produce certain deviations from the healthy functions, and if the effects are sufficiently obvious and characteristic to be recognised by the senses, the practitioner may perhaps be able to form a tolerably correct notion of the nature and extent of the disease. Such signs may be termed the functional signs of disease.

But in many cases such evidences are not only obscure, but even ambiguous, and it would not be difficult to shew that a reliance upon such evidences has led not only to erroneous views, but even injudicious modes of practice. As examples, I have only to recal your attention to the diseases of the chest, which were the subject of our earlier consideration. How many cases of bronchitis have passed for consumption, and how many instances of *false* cure have been handed down to us. The similarity of functional manifestations between (tubercular) phthisis and many of the forms of bronchitis, renders any thing like a correct diagnosis founded upon such symptoms wholly impossible. The immortal Laennec has not only pointed out to us our former errors, but has furnished to us the means of detecting and correcting them. The stethoscope, and other modes of exploration, have enabled us not only to detect the nature of the disease, but to determine almost to a fractional of space, the locality and extent of the morbid condition in the respiratory organs. The information afforded by the stethoscope is valuable, because the conclusions are certain, inasmuch as they are founded upon principles which cannot possibly err. There are certain principles in physics which are almost as certain as the mathematics, and when we have made ourselves acquainted with these principles and their various modifications, we have acquired the means of obviating all sources of fallacy or ambiguity.

A similar mode of reasoning will apply to the diseases to which I am about to direct your attention. The functions of the urinary system exert certain influences on the economy, and so long as these functions continue healthy, the general economy will be preserved from any derangement derived from this source. But if from any unnatural condition of the urinary organs, their functions should be-

come deranged or depraved, the general economy will suffer to a corresponding extent; and as frequently occurs in other cases, the only obvious evidence of disease will be in the general economy itself, or in the functions of some other organs at a distance, and, as it were, unconnected with the primary seat. How often has it happened that incipient diabetes, or diseases of the bladder and kidneys, have been confounded with indigestion; nor has the error been detected, till the mercury administered for the correction of deranged hepatic functions has induced irremediable organic disease, or even fatal disorganization of the primary seat. It is of the utmost importance to keep these facts in our recollection, and not to decide too hastily upon modes of treatment, nor upon a cursory view of the symptoms. A local disease, for instance, may produce but few, if any, and very slight local symptoms, while the constitutional disturbance will be the most prominent feature in the complaint. Were we to adapt our means to the obvious or more prominent character, we probably should have reason to repent our too hasty decision. An examination of the urine will always enable us to determine this point.

The healthy condition of an organ may always be determined by the manner in which it performs its functions. It is the function, for instance, of the liver to secrete bile; of the kidney to separate the urine from the blood. The composition and character of these principles, therefore, will enable us to determine, at least to a certain extent, the healthy or morbid condition of the secreting organ. If a particular or special organization produce a particular effect or function, we cannot conceive any, even the minutest deviation in the properties of the functional manifestation, without a corresponding change in the organism. Hence the secretions and excretions*, or at least the physical and chemical properties, may be regarded as a tolerably correct index of the anatomical condition of the organic structure. There are certainly slight or evanescent deviations, which are but transitory, and consequently indicate nothing of importance; but when the deviations become permanent and more extensive they indicate disease, and require more serious attention. It is upon these principles that

this subject will be treated in the ensuing course.

I have been diffuse upon this subject, because I am anxious to inculcate the necessity and great importance of attending to the state of the urine in these diseases, and not only in the special diseases themselves, but also in the diseases of other organs, and of the system at large. It would be an insult to your understanding to attempt any proof of the first proposition; and your own observation will have convinced you, that the urine presents many deviations from the healthy condition during the progress of other diseases—as well local as general. The altered conditions which this excretion undergoes will often enable us to determine the probable duration or positive termination of febrile diseases; and they also afford no less certain evidence of the morbid state of the organs in mere local affections.

Here, possibly, it may be asked, if so much and so valuable information is to be obtained by attention to the state of the urine, how is it that the subject has obtained so little, at least by no means its fair proportion of the attention of the profession? This may be accounted for variously:—Medical men who have not practically attended to the subject, have imagined that such inquiries require a much greater degree of chemical skill and address than is really necessary for their successful prosecution. But I trust I shall convince you, during this course, that this is a hasty and unfounded opinion, and that even a less degree of chemical address is required for this purpose, than for those toxicological researches which are daily undertaken by all classes of practitioners in medicine. From the above feeling, lecturers and teachers in general do not undertake to teach practically, and by example, the modes of chemically examining the urine, and consequently the student hears merely an enumeration of the functional signs, which, as already observed, are often fallacious, and frequently lead to false notions. A third reason probably is, that the diseases of the urinary system are considered as belonging more exclusively to surgery; and hence the teacher of medicine enumerates them rather as objects essential to his nosological classification, than as proper objects for his department; while the surgeon, on the other hand, treats them only in relation to surgical operation. The late Dr. Marcet was the first to treat this subject scientifically, and the attention which his lectures generally obtained induces me to hope that the subject will not be found wholly devoid of interest on the present occasion. Before, however, entering upon the diseases of this system, it will be necessary to have a

* By secretion is understood any thing separated organically from the blood, and applied to some useful purpose within the body. Excretion is any thing similarly separated, and thrown off as useless or injurious—as urine, sweat, carbonic acid, &c. This excludes the feces, which is a peculiar, and as it were, mechanical separation of the intestinal contents into the *recrémentitious* and *excrémentitious* portions, without entering the blood.

knowledge of the chemical constitution and general properties of healthy urine, that we may be able to distinguish its variations when diseased. In order to study the characters or properties of bodies, they should be arranged according to some fixed and intelligible principle. The properties of the urine may, therefore, be conveniently arranged according to the following relations:—the sensible, the mechanical, and the chemical properties.

The urine is separated from the blood by the action of the kidneys; and as many principles are found in the former, no trace of which can be discovered in the latter, it may be useful first to take a hasty survey of the nature, composition, and general properties of the blood, as this, perhaps, will materially assist us in studying the functions of the kidneys.

Blood is that well-known fluid sent out by the ventricles of the heart to the arteries, by the minute ramifications of which it is conveyed to all parts of the body. In its passage through the different structures, the various secretions and excretions are separated from it by what are termed the secreting and excreting vessels, and it is then returned by the veins to the right side of the heart. The blood in the right side of the heart differs materially, at least in some of its sensible properties, from that in the left. In the former, it is of a deep purple or blackish colour; in the latter, of a bright red or vermillion.

Blood drawn from a vessel, and examined by the microscope, is seen to consist of minute particles, floating in a transparent colourless fluid. These are the red particles, generally named the globules of the blood. They are not, however, globular, but present the appearance of flattened circular discs. The usual mode of preparing the blood for microscopical observation has led to the error as to their globular form. Water, with which the blood is usually mixed, has the property of altering the form of the red particles; but a very dilute solution of chloride of sodium, or of sugar, or even of serum, has no effect of this sort. Of this, and of the flattened circular form of the particles, you may satisfy yourselves by examining blood prepared by each of these methods upon this slip of glass. As I bring them successively into the field of this microscope, you perceive the flattened circular appearance of the one specimen, and the irregularly globular appearance of the other.

The transparent colourless fluid, in which you see the red particles floating in recently drawn blood, is termed the lymph, or liquor sanguinis. This liquor sanguinis must not be confounded with the

serum, from which it differs, inasmuch as it holds the fibrin in solution. But as fibrin speedily coagulates when evacuated from the vessels, it separates in the form of a solid mass, enveloping in its coagulation the red particles, forming what is termed the crassamentum, cruor, or clot; when blood drawn from a vessel separates spontaneously into crassamentum and serum. The fibrin is that white elastic fibrous substance which is frequently observed forming the superficial white crust, termed the "buffy coat" of inflammatory blood. It may be easily obtained by exposing the coagulum in a linen cloth to a stream of water from a pipe. The red particles are thus washed away, and the fibrin is left behind. You see in this specimen the fibrin separated from the red particles by the above process.

Fibrin may also be readily shewn in a separate state by the following process:—If recently-drawn blood be stirred with a rod or twig, and when the blood has coagulated, the rod be washed in water, the red particles will be removed, and the coagulated fibrin only will remain, occupying the interstices between the branches of the twig like a piece of membrane, as you observe in the example now presented to you.

Fibrin may be shewn, also, in its dissolved state. Many saline matters have the property of preventing the rapid coagulation of the blood, and the liquor sanguinis, viz., the serum holding the fibrin in solution may be separated from the red particles by mere filtration. This is most easily shewn in the blood of the frog, the red particles of which are so large that they do not readily pass through white filtering paper.

There are, however, other methods of demonstrating the same fact. Some saline solutions have the property of retarding the coagulation even of human blood. Thus, if we add a few drops of a very concentrated solution of carbonate of potass to the blood of man, or to that of any vertebrated animal, the coagulation will be retarded, and the red particles in the meantime subside. In the space of about thirty or forty minutes a soft coagulum is formed, the under part of which, as you may here observe, is red, from the deposition of the red particles; while its upper portion, as you may see, remains white. Nitrate of potass, and also sulphate of soda, if added to recently-drawn human blood, prevent the coagulation. Here you see an example of this fact: the coagulation here also has been prevented, and the liquor sanguinis remains in its perfect and fluid state.

Fibrin, when coagulated, is soluble by digestion in diluted acetic acid, and is

precipitated from its solution by the ferro-cyanide of potassium.

When the coagulum has separated, we find remaining a yellowish-looking fluid, possessing a slighter degree of tenacity, named serum. Serum has a slight alkaline reaction, from the presence, according to Marcet, of soda. It contains some animal and mineral salts, with some animal principles, the chief of which is albumen. Albumen possesses some analogies to fibrin; but still there are some peculiarities of character sufficiently distinctive. Fibrin coagulates spontaneously shortly after its evacuation from the vessels. Albumen does not coagulate unless its solution be exposed to a temperature of from 150 to 160° Fah., or from the action of chemical reagents. If albumen be cut into slices, and exposed to a gentle pressure, a sort of opaline or slightly opaque fluid, of a saline taste, oozes out from it, which has been named the "serosity" of the blood. No such oozing is observed in

fibrin from a similar treatment. If coagulated fibrin be digested in diluted acetic acid it is dissolved; if to this solution a solution of ferro-cyanide of potassium be added, a yellowish precipitate is thrown down. Albumen is precipitated white, from a neutral or slightly acidulous acetic solution, by ferro-cyanide of potassium; but coagulated albumen does not dissolve by digestion in diluted acetic acid. In the following reactions you will see experimental confirmations of the above propositions:—

Blood, though a homogeneous-looking fluid when first drawn, is evidently of very complicated composition. The specific gravity of human blood is very various, but may be stated to range between 1.015 and 1.055. The specific gravity of serum is estimated at about 1.028; but Dr. Marcet makes it 1.0295. The composition of blood is, therefore, as follows:—

Water.

Red particles } Named by Berzelius
Fibrin..... } the albuminous
Albumen .. } principles.

Lactates of soda, with accompanying animal matter.
Muriate of potass*.
——— soda†.

On incineration, the ashes yield { Oxide of iron, alkaline and earthy phosphates, and sulphates.

The red particles, when burned, yield the oxide of iron and the earthy phosphates; the incinerated albumen and fibrin yield traces of the sulphates and phosphates, but none of iron. From the fact that silver is tarnished by serum, and a sulphuret of the metal formed, it is evident that it contains sulphur. Vogel ascertained, that characters written on paper with acetate of lead, are rendered legible by exposure to the vapour arising from serum heated for several days to between 75° and 96° Fah. Serum kept for some time exhales the odour of hydrosulphuric acid gas (sulphuretted hydrogen,) and blackens the salts of lead, as you may observe in this specimen; which consists of serum about six weeks old, and diluted with four parts of water. On withdrawing the stopper and heating it gently, not only does the odour become sensible, but the exhalation, as you perceive, renders evident these characters written on white paper with a solution of lead. Berzelius therefore thinks, that the phosphates, sulphates, and oxide of iron, evolved by the incineration of the fibrin, albumen, and red particles, were formed during the combustion; and that they existed originally in their most simple or uncombined form, as phosphorus, sulphur, calcium, &c. and iron.

The relative proportions of these ingre-

dients vary considerably, not only in different persons, but in the same persons at different periods. The average proportion of serum to crassamentum is as 3 to 1. The proportion of colouring matter to the fibrin was found by Berzelius, upon one occasion, to be as 1.8 to 1, or nearly as 2 to 1. Physiologists have enumerated other principles in the blood, as *crucorin*, *hæmatin*, &c.‡; but it is not the object here to enter into the minutiae of physiology. I therefore merely state such facts with regard to the physiology of the fluids, as are essen-

* Chloride of potassium.

† Chloride of sodium.

‡ The following elaborate analysis of the distinct substances in the blood has been given in his Thesis, by M. Lecanu. They amount to 25 in number:—

1 Free oxygen.	14 Carbonate of soda.
2 Nitrogen.	15 ——— lime.
3 Carbonic acid.	16 ——— magnesia.
4 Extractive.	17 Lactate of soda.
5 Phosphuretted fat.	18 Fatty acid salt.
6 Cholesterine.	19 Yellow colouring matter.
7 Seroline.	20 Albumen.
8 Free oxalic acid.	21 Water.
9 Margaic acid.	22 Fibrin.
10 Hydrochlorate of potass.	23 Hæmatosine.
11 ——— soda a	24 Albumen.
12 ——— ammonia.	25 Globules, b
13 Sulphate of potass.	

The three last but one constitute the *crucor* clot, or coagulum.

a Chlorides, potassium, and sodium.

b Red particles.

tial to a thorough knowledge of our immediate subject. At our next I shall consider the general properties of the urine as well in a state of health as of disease.

The *urine* is separated from the blood by the *kidneys*, two excreting glandular organs, situated one on either side the lumbar spine, between the spine of the ilium and lowest rib. They are, as it were, buried in the fat of the loins, resting on the quadratus lumborum, and on the *lowest part of the diaphragm*; and I must beg to direct your attention particularly to this connexion, as it will explain a sympathetic symptom to be noticed hereafter.

The kidneys, as you see in these examples, present four surfaces; two broad and irregularly flat surfaces; one sharply convex, pointing outwardly; and that looking towards the spine, deeply notched or sulcated. They lie behind the peritoneum, that is, they are not invested by that membrane, which merely passes before them. They receive their arteries directly from the aorta, and the emulgent or renal veins enter the cava. They have a proper tunic, of a firm consistence, being condensed cellular tissue, almost fibrous. They consist of two parts: one external, named the cortical; the other internal or medullary. The external or cortical is the discerning

part, and consists of the minute ramifications of the emulgent arteries: this is some lines in thickness. The next division is what is termed the medullary portion; it commences with the tubuli uriniferi. These tubuli are continued into conical projections, named papillæ. The papillæ project into the calices or infundibuli, of which the pelvis may be considered as the enlarged reservoir. The pelvis, as it proceeds from the notch, terminates in a membranous tube, termed ureter. The ureters enter the under and posterior part of the bladder, behind the neck, penetrating the coats obliquely, so as to render a reflux of the urine from the bladder almost impossible, as you may observe in the example before you.

The functions of the kidneys consist in separating from the blood that complicated fluid named urine. Urine consists of a large proportion of water, holding, in its healthy state, a number of animal and saline principles in complete solution. Berzelius has carefully analyzed urine, and as his analysis is that mostly adopted by chemists and physiologists, we shall adopt it here. His analysis of one thousand parts of healthy human urine affords the results expressed in the table upon the board, viz.:—

Water.....	933.00
Urea.....	30.16
Lithic acid.....	1.00
Free lactic acid? lactate of ammonia and animal matters inseparable from the above (osmazome, soluble in alcohol; extractive, soluble in water).....	17.14

Healthy urine, recently passed, and while warm, presents the following general characters. It is a fluid of a light amber colour, and perfectly transparent. It has a peculiar odour, somewhat aromatic, and resembling in some measure that of violets. Taste saline, bitter, and rather disagreeable. The specific gravity will naturally vary from very trivial and transient causes. Any cause, the agency of which is to increase the watery portion, without affecting the animal or saline principles, will reduce the specific gravity; while any agency (*relatively*) diminishing the proportion of water, or increasing that

of the saline or other principles, will increase the specific gravity.

In this jar you see some distilled water, into which I immerse this instrument called an hydrometer, and you observe that it sinks to nearly the end of the stem. I now introduce a little common salt; and you observe, that as the salt dissolves, the stem emerges from the fluid and rises above the surface, indicating an increase in the density of the fluid. This is the way in which the specific gravity of the urine increases when the saline principles are increased in relation to the watery portion. But now let me add to this same solution of salt

some distilled water: now you observe the stem sinks, shewing that the density of the solution is reduced by the increase of the water in relation to the saline ingredient. It is thus that watery diluents, administered internally, reduce the specific gravity of the urine, by increasing the secretion of the watery portion. The average specific gravity of healthy human urine has been estimated at between 1.010 and 1.015. I think myself that between 1.012 and 1.017 is the more common range. [Here several specimens were examined in proof.]

The temperature of healthy human urine varies with a variety of circumstances; but the general standard is about 92°. It varies, however, from about 75° to 112° or 120° Fah.

The quantity likewise depends upon a variety of adventitious or accidental circumstances; such are, the nature, quantity, and quality of the food and drink; and these, indeed, have great influence upon all the foregoing properties of the urine. The average quantity, however, may be estimated at between two and three pints in the twenty four hours.

All the above properties you have an opportunity of seeing exemplified in the present specimens, viz. the light ambery colour; the transparency; the aromatic odour, *sensible* only in those specimens which are yet *warm*; the specific gravity, varying as you see from 1.013 to 1.019. The quantity can be ascertained only by collecting and measuring the quantity of urine passed during a definite period, and repeating the experiment several times, with certain intervals between.

The chemical properties depend upon the chemical composition of the urine. Healthy, it reddens litmus paper; and by immersing pieces in these specimens, the blue colour will be changed to red,—as you see.

The aromatic odour leaves the urine as it cools; and in those specimens which have become cold, the *aromatic* odour, as you observe, is no longer perceptible; but you find that another and peculiar odour has succeeded the aromatic. This odour has been distinguished by the term *urinous*. In this specimen, which has been kept for some days, you perceive another change in the odour—a sort of sour smell, and which has been compared by some to that of *sour milk*; it is a sort of sour odour modified by an *animal* one. Lastly, in this specimen, which has been kept till decomposition has commenced with the putrefactive process, a *fætid ammoniacal* odour is very perceptible. This is the odour which is perceived in those public places of frequent resort allotted for relief to this natural call. You also perceive, on exami-

ing these various specimens, the gradual transitions from the most perfect transparency to cloudiness, and an approximation to opacity, and ultimately the formation and subsidence of deposits. Hence you will see the necessity of keeping the urine, that you may observe the changes in the sensible properties, and the rapidity with which they succeed; for from such phenomena much of great importance is often to be inferred:—"Ex his enim, similibusque, sæpe curandi nova ratio ducenda est."

CLINICAL LECTURE

ON

CARBUNCLE—SPONTANEOUS PARTIAL INVERSION OF THE UTERUS—IRRREDUCIBLE OMENTAL HERNIA—INFLAMMATION OF THE HAND FROM INJURIES OF THE FINGER,

Delivered at St. Bartholomew's Hospital,

By WM. LAWRENCE, F.R.S., &c.

GEORGE HAYCROFT, 54 years of age, a mechanic, of good constitution, always enjoying good health, was received into the hospital on account of a carbuncle at the back of the neck, which had begun, according to his statement, a month previously. As no treatment had been adopted except poulticing, it afforded an opportunity of observing the natural course of the malady. It had caused severe pain, swelling of the neck and stiffness, so that he could not turn his head; want of rest, loss of appetite and feverishness. He had not, however, been confined, nor had he entirely given up his employment, even for one day. It had been discharging several days when he came to the hospital. There was an inflammatory swelling, of circular figure, as large as the half of an orange, at the back of the neck. In the centre of the tumor there was a large irregular opening in the skin, exposing cellular sloughs, soaked in matter, and nearly detached. A few small openings were seen in the skin round the larger one; and a healthy, thick, yellow discharge, proceeded from all of them. The inflammatory tumefaction had nearly subsided, the integuments remaining of a dull red as far as the extent of the original carbuncular inflammation. The pain and feverishness were nearly gone; the appetite and rest had returned.

June 28, 1838.—Meat diet; a dose of the senna mixture; linseed poultice.

July 2.—The part to be dressed with the resin ointment.

10th.—Discharged well.

Sarah Gosby, 32 years of age, and unmarried, a person of spare habit, who considered herself of healthy constitution, and had usually enjoyed good health, was admitted into the hospital June 11, 1838. Nine days previously a small painful pimple had formed on the back of the right shoulder. This had gradually increased, with aggravation of suffering, loss of appetite and rest, to the time of admission, when a carbuncle was found at the back of the shoulder, about three inches in diameter, presenting a gentle convex rising, with the integument of a dusky or livid red, surrounded by a broad areola of bright redness. At the centre there was an opening in the skin as large as a split pea, exposing a yellow slough, while around and near it there were several minute round apertures, from which a small quantity of purulent matter exuded. When it was intimated to her that she might be relieved by opening the part, she expressed her determination not to submit to the use of the knife.

Twelve leeches to the swelling; linseed poultice; a dose of opening medicine; milk diet.

12th.—The part is more inflamed; but her resolution respecting the operation is unchanged.

13th.—The complaint still increasing, with severe and incessant burning pain, which entirely prevents rest. She now wishes for any thing to be done that may afford some relief. An incision across the carbuncular swelling in its whole extent, and to the depth of an inch and a half, with a perpendicular cut of similar length and depth, crossing the former at right angles. There was free, but not considerable bleeding from these incisions; and the part was afterwards covered with linseed poultice.

14th.—The patient passed a good night, and is much better to-day. Matter has flowed freely from the incisions; the progress of the carbuncle is stopped, and the surrounding inflammation is lessened.

15th.—The patient looks and feels weak.

Quin. Disulph. gr. ij. three daily; six ounces of Port wine daily. Lint thickly spread with resin ointment to be applied under the poultice.

18th.—The swelling has abated; there is free suppuration, and sloughs of cellular membrane have been discharged. The skin is rather hot, and the pulse accelerated. The wine discontinued: an opening draught immediately.

22d.—Still a little feverish; the complaint proceeding favourably.

The quinine to be discontinued.

From this time recovery proceeded ra-

pidly, but the process of cicatrisation was slow, as the opening in the integuments was large, and the granulations exuberant. She did not leave the hospital till July 24th, when the part was not quite healed, although the health had been for some time completely restored.

Edward Morris, 46 years of age, a stout man of low stature, following the occupation of weaving, in the habit of drinking beer and spirits, indulging sometimes freely, came into the hospital on August 16, 1838, for a carbuncle on the loins. The complaint had existed about three weeks, and he had continued at work till the last three or four days, when he had been prevented by the severity of the pain, which had entirely destroyed rest. The carbuncle was a tolerably regular, firm, convex rising, of circular figure, and fully four inches in diameter, situated in the right lumbar region. The integument, of a dusky red and partially livid hue, was perforated by numerous small holes, through which there was a sparing discharge of matter. The immediately surrounding skin was slightly swelled, and bright red to a considerable extent in the entire circumference; so that the inflammation measured about twelve inches in its longest diameter. The pulse was not much accelerated, and the constitutional disturbance was altogether less considerable than might have been expected with so serious a local malady. I made a crucial division of the carbuncle, the incisions going through the whole extent of the inflamed and thickened mass, which was fully two inches in depth, but not embracing the surrounding areola. Profuse bleeding ensued from numerous vessels, and sixteen or twenty ounces flowed in a very short time, with the effect of dissipating almost entirely the surrounding redness within a few minutes. The bleeding continued, in a greater or less degree, for some hours; and the sister of the ward represented that at least forty ounces were lost altogether, without, however, causing faintness or producing any decided feeling of weakness.

Linseed poultice. Five grains of Pil. Sapon. c. Opio at bed-time. An effervescing saline draught every six hours.

Matter was discharged freely at numerous points. Complete relief from the severe burning and throbbing pain ensued, the patient slept well, and expressed himself as quite comfortable the next day.

17th.—Meat diet.

18th.—Resin ointment to the incisions. Recovery proceeded rapidly and uninterruptedly, and the patient left the hospital quite well on September 17th.

I lately attended a gentleman, between 50 and 60 years of age, with a large carbuncle at the neck. He was of spare habit, with rather sallow complexion, and had long suffered from dyspepsia, for which he had been accustomed to take medicine and pay considerable attention to diet. It was about ten days after the inflammation in the neck began that I first saw him. He had then an inflammatory tumor of brawny hardness, with dull red and somewhat livid discoloration, as large as the palm of the hand, immediately below the occipital ridge on the left side of the neck. This was the seat of severe throbbing and burning pain, which had prevented rest for the preceding week. The head was immovably fixed, and the patient could not have turned it to save his life. There were a few small openings in the skin, with hardly any sensible discharge. I made a crucial incision through the inflamed and indurated mass, which was about two inches in depth. It was followed by profuse hæmorrhage; at least three pints of blood were lost in about an hour, and it continued to flow abundantly. I therefore introduced into the incisions lint, soaked in a saturated solution of alum, pressing it down firmly, and adding other pieces, so as to fill up the cuts. This plan was successful in stopping the bleeding, but diminished the amount of relief usually afforded by the operation, as the suppurative process was checked by the astringent, and the escape of matter was further prevented by the lint, which continued closely adherent for forty-eight hours. Still the patient had some sleep in the first night, the inflammatory mischief was arrested, and in a few days, under the application of the resin ointment, an abundant suppuration was established. The whole of the cellular membrane which had been the seat of carbuncular inflammation sloughed and came away. I removed one mass two inches long by one in width and in thickness. No medical treatment was necessary, except for the purpose of regulating the bowels. In a week the patient had a good appetite, and was able to take nearly a full diet; and at the end of a month he went out for a daily airing in his carriage.

Carbuncle is a peculiar inflammation of the adipose and cellular tissue immediately under the skin, the latter being necessarily involved in the mischief, from its intimate connexion with the other structures. The parts are not only highly inflamed—in a state of the highest vascular excitement, but remarkably indurated, so as to feel brawny and hard, and to afford considerable resistance to the knife. Minute suppurations, in endless number, are dispersed in all directions through this inflamed and indurated mass; we see

them from the size of a pin's head to that of a pea and bean: they contain a healthy matter, which appears in numerous larger or smaller round drops, or can be squeezed out in that form on the surface of incisions. When we consider the number of such suppurations, and the unyielding nature of the texture in which the matter is contained, we can account for the severe throbbing and burning pain, the sense of tension and confinement, and the serious constitutional disturbance, which attend this complaint. Another character of the complaint is the disposition of the inflamed texture to slough. When we make our incisions, we find more or less considerable portions of a yellow colour, indicating the commencement of mortification; such parts are subsequently separated; and the sloughing process not unfrequently affects the whole of the previously inflamed and indurated mass.

The openings, which occur spontaneously in the skin, give issue to the contents of the superficial suppurations only, and do not relieve the part generally. The inflammation, therefore, continues to spread in the circumference, rendering the local malady more formidable, and aggravating the constitutional irritation. Thus elderly persons of unsound constitution sink under the disease, when it has not been efficiently treated at a proper period, and more especially when it is seated in the immediate neighbourhood of the occiput.

Sometimes, however, the carbuncle ceases to spread after attaining a certain magnitude. A large slough of cellular membrane forms in the centre of the swelling; the integument perishes secondarily, in consequence of its vascular supply being intercepted: thus a large chasm is formed in the middle of the disease, which constitutes a convenient outlet for the internal suppurations. This cure of carbuncle by a natural process is exemplified in the case of Haycroft. In Mary Gosby, who would not at first submit to incision, there appeared no probability of the complaint ceasing to spread. In Morris, the carbuncle and the surrounding inflammation had attained the magnitude of a dinner plate, and was still actively proceeding; while in the last instance, of the most dangerous position which the disease can occupy, the indurated inflammation was spreading rapidly, with no signs of natural relief.

Under such circumstances, the only way of rescuing the patient from imminent and serious danger is to make the incisions described in the preceding cases, and to take care that they shall completely go through the carbuncular mass in length and depth. In general this treatment immediately arrests the inflammation; the free bleeding

effectually unloads the excited and distended vessels, while the incisions discharge a great number of the suppurations, and take off the painful tension of the part. The only circumstance immediately connected with the operation that requires attention is the hæmorrhage, which is sometimes profuse, and might be dangerous, although the bleeding vessels are merely those of the adipose and cellular tissue, enlarged and excited by the local disturbance. The depth of the incisions, and the difficulty of separating their sides from the dense and unyielding state of the tissues, renders it nearly impracticable to secure the bleeding orifice by ligature; we must therefore avail ourselves of astringents, of pressure, or of the two means combined. At all events, the patient should not be left until the bleeding has ceased.

Spontaneous partial Inversion of the Uterus.

Sarah Smith, 32 years of age, a maid-servant, was admitted into the hospital on June 12th, 1838. She had always enjoyed good health, and felt herself quite well at the time of her admission. Three years ago she had borne a child, and the catamenia had been perfectly regular since that period. She had menstruated three weeks before she came to the hospital. She represented to me that she had a swelling in the private parts. I found, on examination, a tumor hanging from the external organs, as large as my fist. It was largest in the middle; a little smaller above and below. Observing a transverse fissure in the middle of its inferior end, I at first supposed the case to be a complete prolapsus uteri, but could not recognize the usual appearance of the os tincæ. The surface of the swelling, in its upper two-thirds, was smooth, pale, and nearly dry; this was obviously the vagina completely inverted. The lower third was a soft, almost villous, red surface, moistened by colourless mucus, and was soon recognized by the characteristic folds as the cervix uteri inverted. A defined line marked the boundary between the vaginal and uterine portions of the tumor. She stated that she had experienced a bearing down and uneasiness for five months; that a protrusion had occurred at the external parts for three months, going up of itself after she had lain down at night; that the swelling had been down permanently for the last three weeks, though she had continued to perform her duties as a domestic up to the very day of her coming to the hospital. The mucous membrane of the inverted cervix uteri was healthy, and the cavity of the uterus, into which I introduced the end of my finger, was perfectly so. I could not detect inflammation, enlargement, or any other morbid change.

The exposed membrane had secreted abundantly, for the chemise was completely saturated and stiffened with an almost colourless discharge. My inquiries failed to elicit any circumstances from which the cause and mode of production of this unusual change could be explained. When the patient had gone to bed, I covered the protrusion with a soft cloth, and pressed it upwards with the hand. It was necessary to exert considerable force, under which it suddenly receded, the urine being forced out at the same moment. I introduced my fingers into the vagina, to ascertain that the uterus was restored to its natural state, and that the os tincæ was in its right place. A portion of sponge dipped in a solution of alum was then introduced into the vagina and kept there, the patient being confined to bed. She menstruated at the return of the regular period. She was kept in bed, and used the sponge for three weeks. She was then allowed to get up, still continuing to introduce the sponge. She was discharged quite well on July 25th. I saw her in the latter part of August, when she had again menstruated, and had experienced no return of the protrusion.

Irreducible Scrotal Hernia.

Isaac Hoare, a porter, 43 years of age, has had a scrotal rupture for 14 or 15 years. It was kept up for 12 years by a truss, which he left off six months ago, since which time he has been unable to return the protruded parts. On Feb. 26th, 1838, he felt unwell, and was sick; the bowels being confined, he took some opening medicine, which operated slightly. He came to the hospital on the 27th, complaining of costiveness and sickness, and he vomited after his arrival. The house-surgeon bled him from the arm to thirty ounces, and directed a warm bath. When I saw him in the middle of the day, after the adoption of these measures, the tumor, as large as my fist, was undiminished, but soft, and hardly painful. The abdomen was natural, the pulse quiet; but sickness continued.

Extract Coloc. co. gr. xij. with Hydrarg.

Submur. gr. iij. in pills, immediately; Magnes. Sulph. 3ij. in equal parts of water and Aq. Menthæ, three hours after the pills, and to be repeated every three hours. A common injection with six ounces of scenna mixture to be thrown up after two doses of the mixture have been taken, if the bowels should not have been previously relieved.

The injection was administered in the evening, and followed by copious motions; after which the sickness did not recur.

28th.—No material change in the swelling; it was considered a little smaller.

Ice to be applied to the swelling in a bladder.

29th.—The testicle is swelled, and painful, probably from pressure, in attempting to return the swelling, which descends quite to the bottom of the scrotum.

The ice to be discontinued; twelve leeches to the swelling, and afterwards cold lotion.

March 10th.—The cold lotion has been continued, and the patient has remained in bed: he has taken the solution of magnes. sulph. three or four times a day, and is less reduced than might have been expected, though he complains of weakness and hunger. The principal part of the swelling has returned; but a hard mass, two inches in length, and twice as large as the thumb, remains. This, which is obviously a piece of consolidated and hardened omentum, appears quite loose in the sac; it can be pushed up to the ring, but not through it, even under the employment of considerable force.

To continue in bed, and use cold lotion; to keep the bowels freely open. Meat diet.

In about ten days, as the house-surgeon was examining the part, the lump passed up into the abdomen, under slight pressure. A truss was applied, and the patient was allowed to leave his bed. There was no renewal of protrusion, and he left the hospital in perfect health on March 30th.

In this case, which was obviously an epiplocele, the symptoms were those of incarceration rather than strangulation, and yielded readily to the means usually found efficacious under such circumstances. The patient remained with a large mass of omentum in the scrotum, which had been irreducible for the preceding six months; the indurated mass, which constituted a portion of the protrusion, forming an apparently serious obstacle to replacement. It was very desirable that the parts should be returned, in order to save the patient from a repetition of the inconvenience and danger which he had just passed through. This was accomplished by confinement to bed for three weeks, with cold applications and free purging. In an analogous case of a young man, with an omental scrotal rupture, under my care in the hospital, two or three years ago, the same plan of treatment was equally successful. He was admitted with symptoms of strangulation, which were removed by venesection and aperients, the tumor not being altered. Some part of the protrusion passed up in a few days, but a hardness remained, which, as the patient said, had never been returned. It passed into the abdomen easily after a fortnight's confinement to bed.

Inflammation of the Hand and Fore-arm, from Injuries of the Hand or Fingers.

Ann Portbury, a housemaid, 15 years of age, came into the hospital on May 23d, 1838. A week previously she had pricked her hand with a needle, over the palmar surface of the metatarsal bone supporting the fore-finger. The needle did not enter deeply, and she considered it an affair of no consequence, pursuing her usual occupations. She felt pain in the part the day after the accident, and some swelling took place; it became worse and worse daily, till she came to the hospital. The hand was now acutely inflamed, and swelled to four times its natural thickness. The palm, of which the cuticle was thickened by her laborious avocations, was literally as hard as a board. I could not, on the most careful examination, detect evidence of suppuration, nor find such ground of suspicion respecting the probable presence of matter at any point as would have justified a puncture. Severe pain has entirely prevented sleep for the last two or three nights.

Venesection from a vein of the affected arm; a dose of calomel and jalap; linseed poultice.

Twenty-six ounces of blood were drawn, and slight faintness was felt for a few minutes. The blood was as strongly buffed and cupped as in the case of acute pleurisy; it presented a complete *custa pleuritica*.

24th.—The patient slept tolerably well last night. I found to-day a soft place between the thumb and fore-finger, with fluctuation. It was punctured, and two table-spoonfuls of thick matter were let out, which had formed under the palmar fascia.

27th.—The hand has returned to its natural size, and is quite free from pain.

June 3d.—The opening is closed, and the patient is discharged; there being a very slight stiffness, which would disappear in a few days.

Richard Tarron, 46 years of age, a robust man, and a labourer on rail-roads, came into the hospital June 22, 1838, having had the last phalanx of his middle finger crushed by a heavy mass of iron a week before. The wound was suppurating; the finger generally and the hand were inflamed and considerably swollen; and the fore-arm was red and swelled on its palmar aspect half way to the elbow. He was bled from the affected arm to between \mathfrak{xxx} . and \mathfrak{xxx} .; the blood being buffed and cupped.

A dose of calomel and jalap, followed by a saline draught with \mathfrak{ss} . of Liq. Antim.

Tart. every six hours. Poultice to the finger. Cold lotion to the fore-arm.

Twenty-four leeches to the hand and

fore-arm in the evening. 23d.—Thirty-six leeches.

These measures arrested the progress of the mischief, so that the inflammation of the fore-arm was quite removed, and the general affection of the hand was abated. But the finger continued inflamed and swollen, and mischief spread along the extensor tendon and the theca of the flexor to the palm and back of the hand. It was necessary to use leeches again on July 11th and 13th. Suppuration occurred in the palm and at the back of the hand, at the roots of the injured fingers, and it was necessary to make an opening in each situation. He left the hospital on August 6, with the original wound and the punctures soundly healed. The finger was stiff, but not immoveable: the motion of the other fingers was recovering rapidly.

Another case has occurred lately in the hospital, where general inflammation of the hand and fore-arm had supervened on a slight but neglected injury of a finger. On his admission the patient laboured under considerable inflammatory enlargement of the hand and fore-arm, with red lines running along the arm to the axilla. There was severe pain, with total want of rest. Suppuration took place here among the flexor tendons at the lower and anterior part of the fore-arm. I evacuated the matter by a deep puncture, bled the patient largely from the affected arm, confined him to bed, and followed the antiphlogistic plan in other respects. He was so much improved in a week, that he left the hospital contrary to my advice. In a few days he returned, with a severe relapse of inflammation in the hand and fore-arm, both of which were red, swelled, and almost as hard as a board. They were perfectly stiff, so that he could not move either the wrist or fingers. I told him that he must come into the hospital again, that a much longer treatment would be requisite, and that in all probability recovery would only be partial. Although he assented apparently to my proposal, he did not return.

Numerous cases are seen in this hospital of serious inflammation affecting the hand and fore-arm from slight neglected injuries of the fingers or hand. Suppuration in the palm or at the back of the hand, in the theca of the flexor tendons, among these tendons in the palm, under the annular ligament, and in the neighbouring part of the fore-arm, mortification of the flexor tendons in their sheath are common results of such inflammatory disorders. Hence a finger is sometimes left stiff and extended, from the loss of the flexor tendons; some-

times the fingers generally are contracted and motionless. High inflammation, even without suppuration, often causes condensation of the loose and soft cellular tissue around the flexor and extensor tendons, by which they become agglutinated to each other and to the surrounding parts, with more or less considerable permanent stiffness. When the original injury has been neglected and inflammation is coming on, active antiphlogistic treatment is required to prevent these serious consequences, or to lessen their amount; and we cannot attain the object without employing the same kind of efficacious measures that might be resorted to if an important internal organ were inflamed. Free venesection from the affected limb is the principal measure; after this blood must be taken from the part by means of numerous leeches; general antiphlogistic treatment and rest in bed being combined with these measures.

OBSERVATIONS

ON THE

ACTION OF SOUND IN THE STETHOSCOPE

AND IN THE EXTERNAL EAR.

To the Editor of the Medical Gazette.

SIR,

I CAN scarcely presume to think that every thing novel in the subjoined brief essay on sound is correct; but if it contain a limited measure of truth, this may lead to a more accurate survey of the subject by some of your many able contributors, should you do me the favour to give it a place in your valuable journal.

I am, sir,

Your very obedient servant,

WILLIAM SHAND.

Aberdeen, 23d November, 1838.

I have been induced to commit to paper the following observations, not from any desire to animadvert on the sentiments of the learned gentlemen who, in the *MEDICAL GAZETTE* for 1837-8, differ in opinion as to whether sounds produced in the chest be conducted from the parietes of the chest to the ear by the atmosphere in the stethoscope, or by the fibre of the wood of which it is composed, but to elicit truth and stimulate investigation.

This apparently simple point is not only important in relation to disease in the human body, but in regard to the

action of the sound generally; it is therefore necessary to establish certain practical facts, in order to arrive at general conclusions and truth in this matter.

Sound is usually produced in bodies more dense than the atmosphere, by sudden percussion, and the action of one body upon another; and it is considered to be the result of different modifications of matter only.

Rapid agitation, causing the atoms or crystals of a solid, by their extremities, to act upon each other, creates sound, *whether this action be occasioned by original impulse or by reflection*. It is regulated by the principles of attraction and repulsion; and it cannot be produced, conducted, or reflected, in any case without vibratory action.

As the atoms or crystals of solids vibrate repeatedly, and ultimately return to their primitive positions, they produce more intense and continuous sound than fluids, the component parts of which pass each other, and do not return to their original positions.

In conformity to the density of the atoms, their form, and the medium distance between them, is the intensity, duration, and velocity of sound.

As all sonorous bodies, whilst they conduct, or reflect, also create sound, it is obvious that to preserve the *original character* of sounds, the reflecting or conducting body must in its movements accord in time with those of the body which produces or forms original sound.

As vibration is necessary to produce, conduct, or reflect, every still body must arrest sound, on the same principle that a body at rest, being in contact with a wheel moving round its axis, impedes its progress.

Slow pressure compresses a few atoms only, but rapid percussion occasions action, re-action, and sound, throughout hard bodies.

A solid, to produce much sound, must be of limited diameter in one direction, for it vibrates most in this direction, because the atmosphere yields more than the solid.

In every sonorous body there are two different actions—the tremulous or vibratory action, *which mainly creates sound*; and the undulating motion, which consists of a certain number of atoms moving together.

The undulation, by separating the action of the atoms, also determines the

duration of each distinct sound in a body, and in the organ of hearing. In a string, the nodal point which separates the waves is easily defined; but in an expanded thin body the termination of the wave varies according to the form of the body, and is not easily perceptible; and it is frequently irregular in action and sound, so as to produce confusion in the ear.

For the reasons given, if a rod be struck on the end, or a thin expanded body on the edge, little sound is produced.

The chief distinction between hard solids and fibrous substances is, that the latter possess more of the adhesive, and less of the repulsive, principle; they require to be more distended in a longitudinal and superficial direction; and intensity of sound is more by the extent of their excursions than molecular action.

Fluids are more powerful conductors than producers of sound, but conduct less rapidly than solids. Their atoms or component pass each other, and do not return to their original places, as do those of solids: this accounts for sound passing in all directions in the atmosphere, but most in the direction in which most impulse is given; *also, why the same degree of percussion produces more sound in hard solids than in the atmosphere*; and why, in transit, there is less change in its original character.

It is much influenced by moisture in the atmosphere. Intensity and distance of transit appear to be regulated more by the adjustment of particles than the proportion of moisture. For instance, it is loud and passes farthest during frost, and at all times when objects are seen to a great distance. This is peculiarly perceptible within the tropics, and in this country in summer, just as the sun sinks under the horizon; but when cold increases, and the particles of moisture become larger, these effects are diminished.

It follows, as matter of course, that its transit must be more or less rapid under such varying circumstances.

Water conducts more powerfully than the surrounding atmosphere, and, so far as I have been enabled to ascertain, with increased effect as it approaches the temperature of the human body.

This is exemplified in tropical rivers, and in the human ear, where this fluid is the only body in contact with the

acoustic nerve, to which it must communicate sound consistently with its original character.

The several points to which I have already adverted sufficiently demonstrate why the stethoscope should be hollow in the centre, and of limited thickness in its parts; and why any material pressure on any part of this instrument, so as to compress or alter the natural arrangements in the atoms of the wood, must deteriorate its conducting powers. Were this instrument to press much on the parietes of the chest, the atoms of the softer body must be compressed, and they would sink into the interstices of the harder, and vibration and sound would be checked at the points of contact.

On the other hand, if they be not in contact, a slight separation will produce the same effect in this case, as a crack in a bell, or any other sonorous body; because the air yielding in all directions to the hard bodies, also carries off sound in like manner.

Similar causes must produce similar effects between the stethoscope and the ear.

I hope to be enabled to point out various circumstances to evince, as advanced by Drs. Budd and Cowan, in the *MEDICAL GAZETTE*, that the most dense bodies are not constituted to answer the purposes of the stethoscope, nor in fact in this case to convey sound to the ear consistently with its original character.

To doubt this would be to doubt molecular action, and its effects in sonorous bodies, as partially explained by Dr. Williams, in his fifth lecture in the *MEDICAL GAZETTE*.

As in all hard bodies, sound is produced by agitation, and from every atom; so in passing by the atmosphere in any tube, new sounds being created, and the inflexions meeting in its axis, this must alter the character of the sounds which enter the tube, and make them more or less intense.

Thus copper or wood produces new and intense sounds, pasteboard dull sounds; woollen damps yet more; and any soft, yielding, cohesive substance, damps and arrests sounds. If a room be lined with woollen cloth, the atoms in the atmosphere within the room are arrested in their vibrating action on reaching the cloth, and the whole are affected throughout the room in succession.

Sound is damped in a hard body, on the same principles, when a soft non-elastic substance presses on any part of it; and the influence is more rapid than in the atmosphere, as the atoms are more compact, and do not yield to the same extent.

The sonorous powers of fir do not arise from the lightness of the fibre allowing freedom of excursion, as remarked by Dr. Williams. As well might it be said, that a cork suspended from a sling would vibrate in the atmosphere as decidedly as a leaden ball, or that a ponderous string produces less determined vibrations than a light string.

It is the compactness and tension of the fibre, and the loose and open nature of the material between the fibres, which give it effect and direction.

In a state of vegetation the sap is circulated between the fibrous parts; but when the wood is dry it is replaced by air in the cellular interstices, and the tissue between them becomes loose and open.

The cohesive and repulsive power of the fibre may be known by the great weight that this wood is capable of sustaining by longitudinal suspension, and what it will bear on the end without being materially compressed; whilst the loose texture between the fibres is proved by the ease with which it is compressed or drawn asunder in the reverse direction.

Here we have a concatenation of strings of considerable tension, sufficiently apart from each other to allow them to vibrate, but without so much freedom as to permit them to go beyond a certain distance, and prolong individual action and sound so much as the single string.

The undulations by this means produced in the direction of the fibre, are calculated to conduct and give out distinctly defined sounds, in accordance with the vibratory impressions made on the end of the wood in the stethoscope.

After having, as minutely as circumstances enabled me, investigated the action of sound in every situation and way that occurred to me, as a test of the accuracy or inaccuracy of the conclusions to which my observations had brought me, I determined to analyse the organs of speech and hearing. In this my chief object was to ascertain whether there were any bodies in the ear

to produce prolonged sounds; because, if there were not, neither could such be thrown upon it consistently with speech. I could not, however, reconcile the deductions resulting from my former investigations, with the physical arrangements in the ear, and the popular theory as to the operations of sound in it. What first attracted my notice was the superior surface of the pinna, which varies more in form in different individuals than any part of the human frame; and considering the principles which are supposed to govern sound, it seemed evident that the effects produced by these different arrangements must also be very different; nor could I discover any thing in nature, resembling the pinna, which collected and determined sound to a given point.

Many able physiologists and anatomists admit, that, in certain cases, a portion of sound is conveyed to the internal ear through the solids; but I believe the universally prevalent opinion is, that predominant sounds enter by the aerial passage.

The component parts of the pinna on which sound impinges, except its extremities, are fibro-cartilaginous, the fibrous laminae passing longitudinally into the ear, and the gristle is more brittle as it approaches the temporal bone. In fact its properties are analogous to those of the organs by which sound is produced in the human body, and it is found that all materials of similar tension and of brittle character, whether live or dead matter, are powerful conductors of sound; nor can it reach these without being diffused throughout, if not arrested, by some non-resonant substance, which is not the case in this instance.

I would here remark, that if faint sound produced in the chest, be conveyed by media little sonorous to the walls of the chest, and thence to the acoustic nerve, by what analogical reasoning is it concluded, that exceedingly more powerful impressions being made on any part of the external ear, shall not be conducted by its solids to this nerve?

The construction of the pinna is that of an expanded lever, of which the cartilage around the meatus externus is the fulcrum, and a brittle elastic fulcrum.

The elevations of the helix and anti-helix, are so formed as to oppose and give force to the waves of sound, which

have their proper influence from in front, so as to agitate the pinna. The direction of proper sounds is proved by the fact, that the face is always turned towards the source of sound, and the additional fact, that all intense sounds from behind bring confusion to the sense. It is then remarkable, that the tragus is placed in front, over the orifice in the external ear, so as to prevent the wave from in front directly entering this canal, and to throw it upon the helix or anti-helix, according to the degree of elevation in either, and by which it must necessarily experience new impulse and direction in an acute angle, to convey it to the auditory passage.

This canal, and the anterior surface of the membrana tympani, are lined with cerumen—a peculiarly soft, yielding, and adhesive body, which is calculated to arrest vibration, and its properties are converse to those of the saliva with which the mechanism of speech is lubricated, and without which we cannot articulate.

These are not the only impediments in the way of direct and intelligent sounds entering the ear by the aerial passage, but they do not prevent the atmospheric wave from acting on the membrane of the tympanum, and by means of the chain of bones in the central ear, agitating the mechanism of the labyrinth, and producing undulations in the fluid contained in it.

Whether sound in the stethoscope and in the human ear be conducted by the aerial passages, or by the solids, may be determined by solution of the following abstract principles:—

Do not hard bodies of limited thickness but extensive superficial surfaces, by the action and reaction of their atoms, produce intense and prolonged sounds, in the ratio of their hardness?

Are not sounds produced in such hard bodies *in every case* of rapid agitation, and given out on their superficial surfaces?

Do not the component parts of the atmosphere yield and pass each other, and are sounds of which the ear is sensible produced in these, without their coming in contact with other dense bodies, the atoms of which do not yield in like manner, or pass each other? If then the stethoscope, the interior surfaces of which are sonorous, conducts by the fibre of the wood more than by

its surface, and hard bodies in general are more powerful producers and conductors of sound than the atmosphere, why is it concluded that the solids of the ear do not convey more sound to the auditory nerve than the meatus auditorius, which is lined by a cohesive material, such as nature in no other situation employs as a conductor?

ON GALVANISM,

IN REFERENCE TO ITS THERAPEUTIC EFFECTS ON THE HUMAN SUBJECT.

To the Editor of the Medical Gazette.

SIR,

I shall not recapitulate the numerous writers who have devoted their attention to the effects of galvanism, but take a retrospective view of the practical results of the chief experiments which have been performed. Many of these have been tried under an idea that the muscular system might be acted upon independently of the nerves. Vassali, Juhis, and Rossi, made a great number of trials on decapitated individuals at Turin. Volta and Aldini asserted that the muscular system without the nerves could not be affected, while Fowler has made a contrary statement. In consequence of this uncertainty, many of the present day have failed to produce any beneficial results from the application of galvanism. Ritter has made some remarks on the different effects of the positive and negative wires, stating that the positive pole augments the functions of life, while the negative diminishes them, a statement, I think, not borne out by practice; and my belief is, that the notion of assigning a sedative quality to the direct effect of electricity is not correct; not but that a sedative effect may be the ulterior result of an over-stimulant action on the system. As regards the effects of galvanism on the functions of secretion, Dr. W. Philip has made very satisfactory experiments, so as to set at rest that part of the question, by proving an analogous effect between galvanism and the nerves of organic life. In the *British and Foreign Quarterly Review* for October last are some interesting microscopic experiments, by Dr. Purkinje and Pappenheim, of Breslaw. They have demonstrated a set of mucous glands, which give out the active principle of

digestion or the gastric juice, and also that these glands give out sufficient chloride of sodium, for the digestion of coagulated albumen. They have proved that if the nervous action in the stomach is either identical with or analogous to galvanism, it would be sufficient to account for the secretion of the quantity of muriatic acid requisite for digestion, without the assumption of a special organ of secretion. Dr. W. Philip has related some excellent cases of dyspepsia, where he fully shews the great advantage of galvanism. He states its application to be to assist the nerves of organic life, and not the nerves of volition. In his work on Indigestion, he has published a letter from Mr. Earle, giving a history of some trials of galvanism, which were satisfactory in three cases at St. Bartholomew's Hospital. Breschet has also added to the stock of information in this department*. Thus far has the science of galvanism been applied as a therapeutic agent, with the exception of two cases, published by myself in the 20th volume of the *MEDICAL GAZETTE*, page 70; one a case of partial paralysis of the arm, the other a case of tic douloureux, with some comments which assist in supporting the following remarks. These several deductions appear to me to be the result of my experience:—

1st. Galvanism is identical with the vital action of the nerves of organic life, and the nerves of volition.

2dly. The action of galvanism is determined by the healthy condition of the brain and spinal marrow.

3dly. The skin must possess a normal sensation, as well as temperature, before the galvanic action can affect the muscular fibre.

4thly. The positive plate or wire should be applied over the region of the origin, and the negative to the region of the termination of the nerve.

5thly. The galvanic influence, when passed along the spine, will be most active in the paralysed limb.

* In the fifth number of Guy's Hospital Reports, Dr. Addison relates seven cases of chorea, where a well-directed attention to electricity proved of great service. Dr. A. confesses that he formerly attached as little value to electricity as a remedial agent, as is ascribed to it by the profession in general, being "led greatly to underrate its efficacy in consequence of its vague and indiscriminate recommendation, or from the inefficient and careless manner in which it had been applied."

6thly. Galvanism is assisted by the alkalis and the mercurial action.

7thly. Galvanism restores diminished temperature, decreased circulation, and lost muscular action, in the following order:—Temperature first; circulation second; and muscular action last.

8thly. Galvanism has no effect in disease that alters the structure of nerves.

9thly. It supersedes manual friction.

10thly. It is assisted by the affected limb being immersed in a warm bath, into which the negative plate or wire should be put. In passing a current from the head through one half of the body, the foot should be immersed in warm water.

11thly. It is injurious when much pain is caused in the muscles by its application.

12thly. It may be carried to an undue extent, so as to produce congestion of the brain.

The following cases are related in support of the above remarks:—

Wm. Borkitt, aged 47 years, of middle stature, by trade a shoemaker, applied to me in May 1838, in consequence of a painful affection of the left arm and hand. The extensor muscles of the forearm were nearly paralyzed; the animal heat reduced so that he could not keep the arm warm; the pulse slower in the affected arm than the other. He stated, that during the last twelve months he felt occasional pains, which gradually increased in the outer part of the shoulder, extending down the radial side of the arm to the tips of the fore, middle, and half of the ring fingers. The pain was generally followed by a cold sensation, succeeded by a burning heat and total inability to retain any substance between the finger and thumb. The median nerve, in this case, appeared to be the one principally affected. I ordered him, for the space of fourteen days, to immerse the limb in a mustard bath twice a-day, and to use friction to the arm, with hog's-lard; to take magnesiae sulphatis, ʒij . in a wine-glass of chamomile tea every morning. Still the pain, with loss of power, continued. I then ordered to be used a stimulant embrocation of liq. ammoniae and linimentum saponis, which brought out an eruption of small boils over the whole limb; yet the pain and inability remained. I then gave him the pilula hydrargyri, so as to produce pyalism, which greatly improved

his health, notwithstanding which the inability to use the hand and arm remained the same; but the pain somewhat subsided, and became not so frequent or severe. I now began to apply galvanism, by means of a battery of 24 cups, containing the segment of a circle of plates of copper and zinc, four inches square, immersed in diluted muriatic acid, which being continued daily, from the shoulder to the hand, for three weeks, the pain entirely subsided, the skin regained its normal temperature, and the hand its power. At this stage of the case I deemed it more advisable that my patient should go to agricultural labour before he resumed his occupation as a shoemaker, which he did for the space of two months: by so doing he improved his general strength, and, with the exception of a benumbed feeling at the tip of the middle finger, the use of the hand and arm is quite restored.

Mrs. Ballard, 36 years of age, applied to me May 22d, 1837. I found her suffering from a partial staphylomatous appearance of the eyes, an inflamed conjunctiva, and an extreme sensibility on the admission of light; the upper lids in constant action, with immobility of the iris. On the admission of light it caused pain in the head, over the upper and back part of each parietal bone. The mind much depressed; general debility; the tongue white, with numerous papillae on its surface; bowels torpid; the evacuations deficient in bile; the urine very irregular as to quantity and quality; the skin dry. On my first inspection of this case, I considered the pain in the head and the mental depression to arise in part from hepatic derangement. I ordered her pil. hydr. gr. ij . and acid. nitrici, gtt. ijj . in barley-water, three times a-day; conjoined a milk diet night and morning, with beef-tea or mutton-broth for dinner. This plan had the desired effect of removing the cerebral symptoms, and correcting the functions of the liver and intestines: nevertheless the involuntary action of the upper lids continued, and the extreme sensibility on the admission of light, with almost a completely paralytic state of the iris. I now ordered a tepid shower-bath to be used every morning; to take a more solid diet of animal food without stimulants; to walk, gradually increasing the distance so as not to produce fatigue. I also passed galvanic shocks, from

eighteen cups and three inches square plates, through the upper and back part of the head to the exit of the superior and inferior orbital nerves, and through the temporal bones. At the end of five weeks after using the galvanism, I had the satisfaction to see a steady improvement. The eyelids became regular in their action, and the iris obedient to the ingress of light, and the system generally improved; so that she was enabled to resume her duties as a confidential servant in a highly-respectable family. Previous to the application of galvanism, there was a great diminution of temperature as well as sensation over the whole skin. This case had been submitted to medical treatment in London, for seven months previous to my attendance; and I feel fully persuaded that, without the aid of galvanism, the other measures would have only afforded partial relief. She has remained well up to the date of this paper.

Mrs. Doust, aged 29 years, applied to me March 3, 1835. She had been attacked with paralysis of the left side of the head, face, left arm, and leg. She was the mother of six children, was of plethoric habit, and had had three abortions at the sixth month of gestation. With the use of depletory measures and the mercurial action her health became much restored, with partial use of the hand and leg.

In June 1837, while at work as a penciller in a printing manufactory, she had a most painful spasmodic action of the left arm, which was relieved by a repetition of small doses of ant. tart. and sulphas magnesiae, and leading a more active life. After a time the arm became less useful, so that she could not raise it from her side.

August 1837, I applied the galvanic influence to the arm, but with little or no benefit, as the brain soon became congested, and it was found futile to continue its use.

May 1838, she had another attack of paralysis, with menorrhagia, which I treated with venesection, and assafœtida with neutral salts. The health being restored, I determined on again persevering with the galvanic agency, in conjunction with the use of mercury. Consequently I commenced passing shocks of galvanism from the nape and side of the neck to the arm, with a battery of twelve cups, containing plates the segment of a circle, six inches

by three, immersed in diluted muriatic acid. This method of passing the shocks was attended with great irregularity as to its effect. I then had the foot put into a hot bath, into which I placed the negative plate. (I should have observed, I use two plates, three inches square, which are applied to the surface of the skin, and communicate with the wires from the cups.) The shocks passed more freely down the leg, but were not felt in the arm. Removing the positive plate to the spine, opposite the lumbar vertebrae, I kept the negative plate in the foot-bath. By this application the galvanic action became most powerful in the left arm and hand to the tips of the fingers, producing very violent extension of the arm. At the end of fourteen days I suspended the use of the mercury, and gave her one drachm of the carbonate of iron three times a day, continuing the daily application of the galvanism, by which means she recovered the full use of the leg and arm, but not the fingers, although she could manage to tie a knot.

In this case the cerebral congestion increased according to the increased action of the galvanic agent. It also shews a very singular action of galvanism. I have ventured to attribute this strange effect to the agent passing to the origin of the cervical nerves through the grand sympathetic nerve, as an unusual heat was felt in the stomach and bowels. Certain it is, she only regained the action of the muscles of the arm and hand as the galvanism was passed through the lower portion of the spine to the foot.

May 9, 1838.—Mr. B. H. Goldie, a clerk in the ordnance department, sought my advice in consequence of paralysis affecting the whole of the left side of the body (hemiplegia.) He is a man of full stature, fair complexion, temperament melancholic; he also suffered from an unreduced dislocation of the right os femoris on the dorsum of the ilium, so that he was quite helpless. He stated that about fourteen years ago he slipped off the steps of a friend's house, and ruptured the tendo Achillis of the left leg. In consequence of the passive treatment then enjoined, a gradual loss of voluntary power over the muscles of the left arm and leg succeeded, extending upwards to the half of the head, with diminished circulation, and constant sense

of coldness, not only in the extremities of the left side, but in the side of the chest and body. The left upper eyelid fell so as nearly to obliterate vision. His habits of life were sedentary, and very abstemious both in eating and drinking. The bowels were sluggish, indicative of torpor of the liver; urine generally high coloured, and lessened in quantity. The pulse on the right radial artery 86 in the minute; on the left radial artery 74 in the minute. In this case I, from the onset, had an ulterior view to the application of galvanism, but not until the secretions were corrected. I ordered him to abstain from animal food, and have recourse to a bread and milk diet, and to take—

Pil. Hydr. gr. v.; Pil. Rhei C. gr. v. every night; with a draught in the morning composed of Vin. Colchici, ʒss.; Liq. Ammoniae Acetatis, ʒss.; Sol. Magnesiae Sulphatis, ʒj.

May 16th.—I took eight ounces of blood from the arm, which very much relieved the brain; continued the medicine with the use of the warm bath, at 105° Fah., twice a week until the first of July, occasionally suspending the aperients, according to the action of the bowels, so as not to produce mucous evacuations. I now recommended him to take a wine glass of Griffith's mixture twice a day, and use the flesh-brush to his limbs. The mental depression subsided, and the secretions became healthy, with a more equal state of the temperature and circulation.

July 16th.—I commenced the daily application of galvanism (with a battery of forty-eight pair of plates, three inches square, arranged after the *couronne de tassa* of the French, the plates being circular), passing the shocks from the head, neck, and spine, down to the foot, which was immersed in a hot bath, into which I put the negative plate. During the first week my patient experienced only a gentle warmth, which greatly increased up to the tenth day. The pulse then rose. On the thirteenth day the muscles began to act rapidly and very powerfully, so that on the twenty-first day he lifted the leg and foot out of the bath without aid, and grasped very firmly with the left hand. The galvanism was continued, with increasing power, until it could hardly be borne by the patient; only lessened in effect when he had slight cold or febrile action, from change of weather, &c.

During this process, in consequence of congestion of the brain, I found it necessary a second time to bleed him to the amount of eight ounces.

Aug. 16th.—I discontinued the use of the galvanism, he now being able to walk with a stick and crutch.

Oct. 23d.—He resumed his duties in excellent health, but still with some defect in the muscular power of the left arm and leg. I ought also to observe, that the left leg and foot were oedematous; also the tendo Achillis was much thickened where it had been ruptured: this also was reduced.

JOHN GRANTHAM.

Crayford, Kent, Nov. 21, 1838.

ON THE DIVISION OF THE PROSTATE IN LITHOTOMY.

By H. M. PHILLIPPS,

Assistant-Surgeon to the Royal Cornwall
Infirmary.

A SENSE of duty induces me to communicate to the profession, through your journal, a fact of some practical importance, which I hope will benefit my fellow-creatures, by diminishing the risk of life usually attending the lateral operation of *lithotomy*. The dangers to be apprehended from which are, hæmorrhage, puncture of the rectum, peritoneal inflammation, with purulent deposition about the neck of the bladder; and infiltration of urine, with its consequences. All these may be avoided, as I consider, by adopting the following *modification* of the operation, which I now strenuously recommend to all operating surgeons.

Having introduced a straight grooved staff into the bladder, and having reached the membranous portion of the urethra by the usual incisions on the left side of the perineum, I cut into the groove of the staff. The staff being still firmly held by an assistant, I introduce the nail of the fore finger of the left hand into the groove, then insert the point of the knife also into the groove in advance of the finger, its flat surface resting on and parallel to the plane of the nail; both are then carried steadily onward until the knife enters the bladder, indicated by the gush of water; it is then withdrawn, and the *finger* alone is pushed firmly and

fairly into the bladder. The forceps is then introduced upon the finger (the best director in all operations), and the stone is embraced.

It will be seen that the principle acted upon here is the same as that which proved so successful in the hands of Cheselden, and was so warmly commended by Sir Astley Cooper; namely, the partial separation of the upper from the lower portion of the prostate gland with the knife, completing the separation to the necessary extent without a cutting instrument. Cheselden used for this purpose the blunt-curved gorget; I use *the finger*. And I do declare, having tried this method on the adult, I have found no difficulty whatever in enlarging the opening sufficiently, by simply protruding the finger into the bladder, which is accompanied with the sensation of a slight tearing.

The advantages of this mode of operating are—the certainty of avoiding hæmorrhage, or of puncturing the rectum, and the equal certainty of being able to make the opening into the bladder large enough to extract the stone, and no larger. I may add, that I never yet found any perineum too deep to prevent my enlarging the section of the prostate with the finger; and I am quite satisfied that any lithotomist who may adopt this method will not readily abandon it.

Truro, November 22, 1838.

FRACTURED CLAVICLE.

To the Editor of the Medical Gazette.

SIR,

THE following case of fractured clavicle came under my care soon after reading, in the last volume of the MEDICAL GAZETTE, the papers upon this subject, signed "Observer," and "F. C. Moseley, M.R.C.S." And as my case, besides possessing an individual interest, may throw additional light upon the dispute between your two correspondents, I shall feel greatly obliged by your giving it a place in your valuable journal.

I am, sir,

Your obedient servant,

CHARLES HAYES HIGGINS,
Surgeon.

Taunton, Nov. 26, 1838.

On Thursday, October the 18th, Edwin Hiett, aged six years, was brought to me by his father, having met with a severe fall on the previous evening, whilst swinging on a chain suspended between two posts. He was jerked off the chain and thrown violently against a stone step, the edge of the step coming in contact with the centre of the clavicle.

Having removed his shirt, I perceived the right shoulder to be depressed, and a slight prominence at about the centre of the clavicle. By running my fingers from the sternum along this bone, I found at its centre a distinct crepitus, and a depression of the outer half of it. Having satisfied myself of the existence of a *straight* fracture, and recalling to mind the case related by "Observer," in the number of your journal for May 26th, I desired the little fellow to scratch his head with the hand of the injured side, and to my surprise he did so immediately. At my request he then placed the same hand on his face, and also carried his arm backwards. In fact, the only motion he was incapable of performing with the injured limb, was its extension forwards, as in the act of shaking hands. In answer to my question, he said he felt no pain, unless he allowed the limb to hang down, or attempted to advance it to the front, when he suffered considerably.

Having shewn the case to my medical friends, William Beadon and James Robert Mosse, Esqrs., surgeons, of this town, each of whom separately examined it, and gave their testimony to the fracture, as well as to the anomalous nature of the case, I proceeded to apply Desault's axilla pad and bandages, as modified by Mr. Liston, and at the end of three weeks my little patient was completely cured, having regained all the motions of the limb.

IODIDE OF IRON IN MESENTERIC DISEASE.

To the Editor of the Medical Gazette.

SIR,

HAVING lately had several cases under my care of diseased mesenteric glands treated with small doses of iodide of iron, at the same time giving sulphate of potass in combination with rhubarb,

I beg leave to lay before the profession, by means of the *MEDICAL GAZETTE*, the first case in which I tried its effects, and proved its efficacy. If you consider it sufficiently interesting to merit insertion, you will oblige

Your obedient servant,
WILLIAM GARLIKE.

42, Theobald's Road.

On the 23d of July, 1838, I was consulted respecting the health of Mary —, in the sixth year of her age, who was, by her mother's account, a very healthy child till about four months previously, when her appetite began to fail her; she became peevish and fretful; bowels alternately relaxed and costive; and from which time she has been gradually losing flesh. When I first saw her she was labouring under diarrhœa; feces tinged with blood; abdomen tumid, and painful upon pressure; skin hot; tongue dry and red; muscles flaccid; great restlessness; starting in sleep; no appetite.

R Hyd. c. Creta, P. Rhei aa. gr. iv. sumend. omni mane.

R Decoct. Hæmatoxali ʒiv. Cretæ ppt. P. Acaciæ aa. ʒss. Tr. Cinnamomi ʒi. M. ft. Mistura. Detur ʒss. alt. hor.

These medicines were continued, though at longer intervals, till the 28th, when, the urgent symptoms being relieved, they were omitted.

On the 2d of the following month (August) the diarrhœa had returned, and all the other symptoms seemed aggravated. Recourse was again had to the remedies before used, with a like beneficial result.

On the 17th of the same month she had a second relapse, which was again palliated with similar remedies.

I saw nothing more of this patient till the 23d of September, when the diarrhœa was incessant; pulse hardly perceptible; restlessness; could not bear to be moved; eyes sunken, presenting a leaden appearance; lips parched; tongue and gums dry and glazed; breath hot; abdomen painful upon the slightest pressure (even that of the clothes); flaccidity of the whole muscular system; indeed, the mother had given up the patient as lost, and I confess I had no more favourable impression upon my own mind. To continue the same medicines was useless, as they merely produced an

alleviation of some of the symptoms, the cause not being removed.

R Potass. Sulphatis, Pulv. Rhei aa. gr. iv. omni mane.

R Ferri Iodidi, gr. iiss.; Syr. Simp. ʒij.; Aquæ, ʒx. M. ft. Mistur. cujus cap. ʒj. ter die.

27th.—Medicines have been duly administered; bowels are become more regular, but the patient is in other respects no better. The medicines were ordered to be continued, $\frac{1}{2}$ gr. more of the iodine of iron being added to the mixture. About ʒj. of the following ointment was also desired to be rubbed over the abdomen, once in the day.

R Iodini, gr. j.; Potass. Iodidi, ʒss.; Unguent. Simp. ʒiv. M. ft. Unguentum.

Sept. 1st.—Bowels regular; in other respects no better. The ointment having produced irritation, was discontinued. The mixture was continued, but the powders were omitted.

10th.—Bowels still act regularly; abdomen not quite so painful upon pressure; appetite slightly improved.

It would occupy too much time and space unnecessarily to detail the symptoms on each successive visit, suffice it to say that the iodide of iron was regularly administered till about the middle of October last, with decided advantage, and that now my little patient enjoys as good health as before her first attack.

November 28th, 1838.

IMPROVED METHOD
OF
APPLYING THE TAXIS IN HERNIA.

To the Editor of the Medical Gazette.

SIR,

I SHALL feel obliged by your inserting the following case of strangulated hernia, reduced by Dr. O'Beirne's "improved method of applying the taxis," if you think it worthy of a place in your valuable journal.

I am, sir,

Your obedient servant,

JOHN GRANT WILSON,

Senior Surgeon to the Bristol
General Hospital.

Bristol, Nov. 28, 1838.

I was sent for on the 20th instant to see William Child, a sailor, on board a

small vessel trading between Bristol and Zenley. I found him an athletic man, of dark complexion, aged 34, with a very large scrotal hernia on the right side.

For two years he had worn a truss, which had latterly become insufficient to prevent the descent of the hernia under any extra exertion; but he had always been able to replace it, in the recumbent position, until the preceding afternoon, when, on straining at his work, the swelling became considerably larger, and much more painful. He tried to replace it, but could not. Vomiting soon came on, and he passed a night of great suffering. It was ten o'clock A.M. when I saw him. His countenance was anxious; his pulse small and frequent; the tumor was tense, and very tender to the touch; and the skin of the scrotum reddened. He had hicough, and retched or vomited incessantly; and he had not passed fæces for three days. I could not judge of the nature of what he vomited, as he discharged the contents of the stomach in a bucket of dirty water. I placed him on his back with his knees elevated, and immediately applied the taxis in the usual way, but without avail. I repeated it again and again, using as much force as I thought safe, and as much, indeed, as the painful state of the tumor would admit of, but all in vain. As the symptoms were now urgent, and evidently getting more and more so, I thought of removing him on shore, in order that he might be more conveniently situated for the operation, which I considered it more than probable he would have to undergo: but before doing so, I determined to try the plan of treatment proposed by Dr. O'Beirne, whose very interesting paper, in the *Dublin Journal* for September last, I had recently read. Accordingly, I procured an elastic tube, such as he recommends, thirteen inches in length; and having straightened it, and oiled its extremity, I introduced it into the rectum. It passed, with little or no obstruction, the whole of its length; but as no flatus escaped, I then attached it to the syringe, and threw up nearly a quart of water, in which two table-spoonfuls of common salt had been dissolved, with an ounce of oil added. This enema quickly returned; but as he was obliged, for want of better convenience, to use the bucket, I was unable to see whether

much fæculent matter had passed off. On his again lying down I applied the taxis, but no change was perceptible in the tumor. Feeling assured that I could have passed the tube higher had its length allowed me, I sent for the œsophagus tube of the stomach-pump, and introduced it, with the same ease, more than three-fourths of its length, taking care to pass it very gradually, and upon the least obstruction to attach it to the syringe, when one or two smart strokes of the piston, sending a jet of water through the tube, immediately overcame the difficulty, and allowed it to pass on with ease. When rather more than eighteen inches of the tube had been passed up some flatus began to escape, and on examining the tumor I found it evidently less tense; the man expressed himself in some degree relieved, and the vomiting ceased. I had withdrawn the tube to allow him to pass off the water which had been injected to facilitate its passage; and this time I observed, that nothing but the clear water returned. I then again introduced the tube to the same length, when flatus escaped through it and by the side of it. I then turned the patient on his back, and found the tumor was sensibly diminished, before I began to apply the taxis, and now, with very little difficulty, I was enabled to return the greater portion. About one-third of its bulk resisted my pressure for a few minutes longer, and from its feel seemed to be omentum; but in less than ten minutes from the last introduction of the tube, the whole was reduced, and all the urgent symptoms ceased at once.

The man now requested to be allowed to go to stool, and passed a large quantity of fæculent matter.

I then replaced him in his berth, and applied the truss, and ordered him a five-grain calomel pill immediately, and a dose of castor oil in four hours afterwards.

When I saw him in the evening I found him comparatively comfortable, although he still had some nausea. The pill had operated so briskly that he had not taken the castor oil; I therefore ordered him an opiate, in an aromatic vehicle, to be taken immediately.

The next morning I went on board to see him, and found him out and at work. He told me he slept all night, and awoke quite well, though feeling rather sore. His pulse was below 80,

and the abdomen quite natural to the feel, and not at all tender. In fact, excepting weakness, he had nothing to complain of; and the same evening the vessel put to sea.

This case so closely corresponds with those detailed in the paper already referred to, that I must confess myself now fully convinced of the efficacy of Dr. O'Beirne's plan of treatment in cases of strangulated *intestinal* hernia. It is true that I did not try tobacco enema, and other usual remedies, but my former experience has taught me that they rarely, if ever, succeed when the tumor is so large and tense, the structure apparently so firm, and all the symptoms equally urgent. I certainly believe, that in this instance they would have failed; and although I should have used them, as a matter of course, before resorting to the knife, yet my firm conviction is, that, but for the elastic tube, the operation would have been inevitable. I wish also to state, that my observation in this case perfectly agrees with Dr. O'Beirne's explanation of the *modus operandi* of his remedy. It was not the injection of fluid that produced the benefit; this, no doubt, might have been serviceable in clearing the lower bowels of feces, and was more especially useful in facilitating the introduction of the instrument; but it was not until the tube had passed up sufficiently high to liberate the flatus, that relief was obtained. The moment the pent-up air found a vent all difficulty in the reduction ceased. I cannot conclude without expressing my opinion that the profession is under great obligations to Dr. O'Beirne for making so important an addition to our list of therapeutic agents in these distressing cases; and I have much pleasure in giving my humble testimony as to its value, and in assisting to award the meed of praise where it is so justly due.

ON THE ACARUS SCABIEI.

To the Editor of the Medical Gazette.

SIR,

THE existence of a minute insect infesting the persons of those labouring under scabies, has been alternately admitted and denied; but though many have described its form, some have left

unnoticed its habitât, while others have incorrectly described it; to this we must probably refer the uncertainty which has at various times prevailed with regard to its existence. But whatever doubts may have been entertained formerly, they must have been completely removed by the repeated extraction of the insect within the last four years, before crowded assemblies, at the Hôpital St. Louis; not to mention the host of writers who have given an account of it in the medical, and other journals of Paris. So hackneyed has the subject become, and so little disputed, at least in France, that I should not have deemed it necessary to occupy your valuable pages with what I imagined to be so generally known and admitted in this country; but having lately been present at two microscopic *soirées*, where I was expected to contribute my mite to the general fund, I brought with me one of the little insects in question, and then learned that its existence was not such a matter of general belief as I had supposed. Trusting, sir, that you will consider this a sufficient apology for filling up those pages which should be devoted to more original matter, I proceed to give a sketch of the history of the *Acarus scabiei*.

The first person who makes mention of it, is one Avenzoar, or Abinzoar, a Hispano-Arabian physician, of the twelfth century; and we meet with no further notice of it till the sixteenth century, when it is referred to by Scaliger, Ingrassius, Soubert, Galbricius, and Aldrovande; but the first and last of these writers appear to be the only two who were well acquainted with it. In 1634, Mouffet thus speaks of it: "*Animalculum est omnium minutissimum**, solens nasci caseo, et cere inveteratis, et cuti item humani. Anglice *mites* in caseo foliis, ligno acido, atque cerâ; sed in homine *ached* *uorms* dicuntur, et Germanice *seurin*. Ita sub cute habitat, ut actis cuculis pruritum maximum loco ingeneret, præcipue manibus, vel aliis partibus affectis et igni admotis. Extractus acu et super ungue positus, movet se, si solis etiam calore adjuvetur. Altero ungue pressus hand sine sono crepat, aequumque virus reddit; nigricat vel nigro parum rubet. Mirum est quomodo tam pusilla bestiola nullis quasi pedibus incedens, tam

* Theatrum Insectorum, 1634, Cap. 24, De Syronibus, &c.

longas sub cuticula sulcos peragat. *Hoc obiter est observandum, Syrones istos non in ipsis pustulis sed prope habitare.* Neque Syrones isti sunt de pediculorum genere; nam illi extra cutem vivunt, hi vero non."

Although it is obvious, from the preceding quotation, that Mousset has confounded together different species of acarus, yet I think there can be no doubt from the context, that he was well acquainted with the true acarus of the itch; and we must attribute this confusion to the want of good optical instruments at the period at which he wrote. In 1657, Hauptmann*, a German physician, gave an inaccurate figure of the insect; and six years after it was again described by Hafenreffer†; but the most complete account, and the best engraving of it we have hitherto met with, are by Bonomo, in a letter to Redi, part of which was republished by Dr. Mead, in the Philosophical Transactions‡. Notwithstanding the apparent good faith with which Bonomo relates his experiments, and the circumstances which first induced him to perform them, I fully concur in the opinion of Dr. Adams, that the accuracy of Bonomo's assertions must be doubted, as he pretends to have extracted all his acari from the vesicles. It is from this period we date the error of supposing the insects to inhabit the vesicles, an error which has been copied by nearly every writer on this subject to the present time. The first person who classified it was the celebrated Linnæus, under the name of *Acarus humanus subcutaneus*; but in the second edition of his *Fauna Sulcica*§ he fell into the error of confounding it with the *Acarus farine*; and attributes the occurrence of scabies in infants to the practice of sprinkling flour on the excoriated parts in intertrigo: hence, says he, "*Farinæ et scabiei acaros unam constituere eandemque speciem concludimus.*" It is remarkable, however, that immediately after the *Acarus siro*, under which name he includes the *A. scabiei*, the *A. farine*, and the *A. casei*, he places the true itch insect, the *A. exulcerans*; this can only be explained, as was pointed out by the learned editor of the London Medical

Journal, by supposing that Linnæus believed in the existence of two kinds of itch insect, each of which was capable of producing its own species of scabies*, a mistake which probably originated in the erroneous opinion he had adopted with regard to the production of this disease by means of old flour, and which he never afterwards corrected in the subsequent editions of his works. Degge† was the first who pointed out this error of Linnæus; he gave a faithful description of our insect, as likewise of the cheese and flour mites, with an accurate engraving of the three. He thus defines it:—"Mite arrondie blanche, à courtes pattes rondes, avec un très-long poil aux quatre postérieures, et dont les quatre tarsi antérieurs sont en tuyau terminé d'un petit bouton."

Passing over Baker‡, Wichman§, Adams||, and others who have interested themselves on this subject, I pause at the remarkable work of M. Galès¶. This gentleman, who, in 1812, held the situation of pharmacien at the Hôpital St. Louis, and no doubt was itching for fame, gives the following account of his first experiment:—

"Je plaçai sous le microscope, dans un verre de montre, une petite goutte d'eau distillée, et dans laquelle je m'assurai préalablement qu'il n'y avait aucun animalcule visible; je délayai dans cette eau avec le point d'une lancette, le fluide exprimé d'un bouton de gale que je venais d'ouvrir; mais ce fut en vain que je scrutai de l'œil le plus attentif toute l'étendue de la liqueur, pendant plus de dix minutes, je n'y peux découvrir que des ombres informes, et dont aucune ne ressemblait à quelque chose d'animé. Le même petit appareil, préparé dans deux autres verres, ne m'offrit rien de plus. J'allais terminer la séance presque rebuté de mon peu de succès, quand l'idée me vint de remettre sous le microscope, et d'examiner de nouveau

* This opinion is grounded on the following passage from the *Exanthemata Viva* of Linnæus:—"In scabie farina acari ægrius inveniuntur; exemptos vero, aliam esse speciem (*A. exulcerans*) et pedibus quatuor posticis, corpore duplo longioribus, distinctos." See also his *Syst. Naturæ*, 12th edit. p. 1024; and his *Fauna Sulcica*, before referred to, p. 481-2.

le fluide contenu dans le premier verre, qui, depuis le moment que je l'avais retiré, était resté exposé à la chaleur du soleil. Je fus agréablement surpris de voir un insecte vivant, qui remuait vivement les pattes, cherchait à se dégager de l'espace de vase où il était en-bouché, et qui bientôt, parvenu dans la partie limpide de la liqueur, montra si distinctement toutes ses formes, qu'un des témoins de l'observation, M. Patrix, en dessina sur-le-champ la figure d'une manière très-ressemblante."

Unfortunately for the reputation of M. Gales, his itch insects, of which he affirms to have extracted above three hundred, proved to be nothing else than cheese-mites. His researches, notwithstanding, appear to have created a great sensation at Paris, and, as M. Gras observes, for six years every body believed in the acarus; but the investigations of M. Biett*, in 1818 and 1819, and Mouronval†, in 1820, made on a large number of individuals, and with the best microscope, completely failed in detecting it in a single instance; and henceforth its existence appears to have been treated as a fable. However, the object in dispute, which had occupied so much of the time and thoughts of the savans of Paris, appears to have been familiarly known in the isle of Corsica, where the common people affected with scabies were in the constant habit of extracting it. M. Renucci, a native of that island, who was studying medicine at Paris, first demonstrated it to a crowded audience attending the lectures of M. Alibert, on the 13th of August, 1834. Since that period it has been so frequently extracted, and by so many individuals, that its reality can be no longer a matter of the slightest doubt.

Having thus given an imperfect outline of its history, I beg to present you with the accompanying drawing of the *A. scabiei*, magnified 180 times. By placing in conjunction with the engraving the following description of it by M. Raspail, the reader will be able to judge of its fidelity:—

"Corps un peu arrondi, comme comprimé sur ces deux faces, et imitant la tortue; blanc, strié, hérissé sur le dos de papilles rigides. Huit pattes, les quatre antérieures placées à côté de la

tête et comme palmées; les quatre postérieures distantes. Les quatre pattes antérieures, au moins, sont munies d'ambulacrum."

[Having one already executed, we have used it instead of Mr. H.'s.—Ed. Gaz.]

From the numerous little coniform processes which are scattered over the back of this insect, each of which is said to be surmounted by a fine hair, and from the obliquity of their direction backwards, the reader will perceive the impossibility of the insect pursuing a retrograde course after he has once opened himself a passage beneath the cuticle.

By a reference to the works alluded to in this letter, the reader will observe that their authors differ as to the situation in which the insect in question is to be found; some asserting that it is in the vesicles, while others affirm that it is in furrows in the neighbourhood. I have introduced two rather long quotations from the works of Moutet and Galès, because they may be considered as

* Maladies de la Peau, par Cazenave. Paris, 1828.

† Recherches sur la gale. Paris, 1821.

the representatives of these two opposite opinions. It is now a well-ascertained fact, that in the fluid of the vesicles no acari can be found; to discover them, we should select patients affected with the vesicular form of scabies, and who have undergone no treatment. In some of these there will be observed, in the neighbourhood of the wrist and about the fingers, delicate black lines, varying in length, from an inch to the twelfth part of the same, and pursuing either a straight or tortuous direction. One extremity of these lines is usually less defined than the other, and sometimes terminates in a minute vesicle; they resemble somewhat the scab which is formed on a scratch produced by a fine-pointed instrument, or the black lines frequently observed about the wrists of the lower classes, from the accumulation of dirt in the rugæ of the skin. Hence, to avoid error, it is well to wet the part where these lines are observed, to assure oneself that they do not originate from the cause last specified: having ascertained this, the epidermis at one of the extremities of the line must be gently raised with the point of a pin, and if unsuccessful in discovering the insect, it should be searched for at the other extremity, for *in no other situation can it be found*: there will now probably be perceived at the point of the pin a minute, somewhat globular, *transparent* object, which, on attentive examination, will not unfrequently be observed to move; but even when no movement is perceptible, it can be readily distinguished from a piece of cuticle or other matter, by the *opaque colour* and irregular form of the latter. But, sir, having already exceeded the limits which are usually allotted to subjects like the present, I will, with your permission, reserve what I have to say on the ætiology of scabies for a future number of your journal.

I am, your obedient servant,

C. HOLTHOUSE, M.R.C.S.,

Surgeon to the St. Pancras General Infirmary.

INHALATION OF CARBONIC ACID.

To the Editor of the Medical Gazette.

SIR,

ENCLOSED I send you the *post-mortem* appearances of George Bell. I was

most ably assisted by my friends, — Busk, Esq., of the Dreadnought (Seaman's Hospital Ship), and — Sherwin, Esq., of Greenwich. The appearances before death were those of a person labouring under apoplexy, with constant spasms of a tetanic nature: coma and aphonia prevailed from the moment he was taken out of the pit until death, which took place 80 hours after the accident. The blood drawn from the arm was of the colour of preserved damsons. The case and treatment will be laid before the Kent Medico-Chirurgical Society on Monday, the 17th instant. The post-mortem did not take place till after the inquest. It was kindly allowed by the widow and friends of the deceased.

I remain, yours respectfully,

RICHARD C. HORE.

Blackheath Hill, Dec. 6, 1833.

Account of the appearances noted in the body of George Bell, at. 38, whose death was occasioned from the inhalation of carbonic oxide, &c.

Inspection 40 hours after death.

1. Body muscular, considerably emaciated, extremely rigid; light purple posteriorly, with large white spaces where pressure had existed; many small, irregular, purple blotches on the anterior surface of the thighs, groins, and abdomen, and a few on the chest and arms; slight greenness in the flanks. Countenance pale; pupils dilated.

2. Scalp thin and bloodless; vessels of dura mater congested, and all the sinuses full of blood; general fulness of the vessels of the pia mater; the basilar artery, and the arteries of the corpus callosum, were full of coagulated blood; arachnoid transparent, slight sub-arachnoid effusion in the depending parts. About one drachm of clear fluid in the lateral ventricles; choroid plexus very pale, containing a few serous vesicles; cerebral substance everywhere of normal appearance and consistence, presenting large, but not numerous, bloody points in the posterior lobes of the hemispheres. About 6 drachms of fluid remained in the base of the cranium after the brain was removed.

3. Both lungs perfectly free; no fluid in the pleura; lungs hardly at all contracted, pale and emphysematous anteriorly, of a light purple colour posteriorly, every where crepitant; tissue not infiltrated, light, and of normal consistence; laryngeal and tracheal mucous

membranes pale and smooth, becoming somewhat vascular about the bifurcation of the bronchi, but it was perfectly smooth and healthy, though purplish, in the minute tubes. The trachea contained a small quantity of light white salivary froth.

Pericardium and heart perfectly healthy, not contracted; some dark grumous coagula filled the right cavities, mixed with a small fibrinous clot; the left ventricle contained a very small quantity of dark clot. The blood contained in the large vessels was coagulated and dark.

4. Anterior half of the tongue was covered with a thick light grey-coloured crust, which was easily detached. Mucous membrane at the base of tongue and in the pharynx slightly vascular; follicles at base of tongue somewhat developed, and the epithelium on the sides of the pharynx slightly detached. Œsophagus healthy. Stomach contracted, containing a considerable quantity of bilious fluid, by which the mucous membrane was deeply stained, the stain being deepest on the rugæ; otherwise the mucous membrane was pale, and of normal thickness and consistence, somewhat mammillated towards the pylorus.

Small intestines were perfectly healthy throughout; no development of Peyerian patches at the end of the ileum.

Large intestines. Mucous membrane of the cæcum of a deep purple colour, as if ecchymosed, but of normal thickness and consistence; elsewhere the membrane was pale, and perfectly healthy. The large intestine contained a large quantity of soft fecal matter; fluid in the cæcum.

Liver of perfectly healthy appearance and colour.

Gall bladder full.

Kidneys dark coloured from congestion; otherwise perfectly healthy.

Bladder empty, and firmly contracted.

REMARKS

ON WHAT IS USUALLY CALLED THE

SPONTANEOUS AMPUTATION OF THE LIMBS

OF THE FŒTUS IN UTERO.

By JOHN ROSE CORNACK, M.D. &c.

In all circumstances, and in every situation in which organizable lymph is effused, it is observed, after the lapse of

a certain time, to contract, and exhibit a tendency to bring the parts with which it is in contact into closer proximity. The contraction of cicatrices is a familiar illustration of this; and pathological anatomy furnishes us with numerous other examples. When there is effusion within the cavity of the chest, the danger consists not only in the injurious effects upon the viscera produced by the pressure of the fluid, for after this has been removed either by an operation, or by the process of absorption, and the lungs have perhaps regained their natural freedom of play, it may and sometimes does happen, that from there remaining a layer of lymph spread out upon the pleura pulmonalis, a false membrane is formed, which ere long, from its contraction, produces permanent atrophy of the lungs*. If the patient live a sufficient time, the air-tubes and blood-vessels become obliterated, and instead of finding an inclosed lung within the capsule, there is only to be seen a small mass of cellular tissue. When the extent of the inflammation is limited, and the consequent effusion also circumscribed, it is not unusual to find only a lobe, or even a portion of a lobe, diminished in bulk. It sometimes happens that a band of lymph strangulates a portion of lung, by preventing the blood to pass through its vessels. Carswell has given representations of portions of lung atrophied, or even nearly amputated, from this cause.

Constipation is frequently observed to follow chronic peritonitis, and is to be accounted for by the lymph effused forming bands, which mat together, and compress portions of the intestinal canal. Compression sometimes takes place in this way to an extraordinary extent. It occasionally happens that a false membrane is found extending over the whole peritoneal envelop of the abdominal viscera, causing atrophy of all the contained organs. The stomach and intestines, liver, spleen, and urinary bladder, are often from this cause compactly bound together, and firmly tied to the

* It must be remembered that although mucous membranes, when in a state of integrity, never throw out organizable lymph, serous surfaces exude inorganizable as well as organizable lymph. The former is often seen at post-mortem examinations, and may at once be distinguished by its colour, as well as its glutinous rosy-like appearance. This inorganizable lymph, it has been remarked, sometimes produces by its presence as a foreign body such irritation as sets up a new inflammation. The opinion is entertained by some that tubercle, pus, and inorganizable lymph, are all modifications of the same thing.

spine. They may be variously grouped, or some particular organ or organs may be more compressed and atrophied than the rest*.

The contraction of cicatrices and false membranes might well form the theme of an extended memoir, but my present object is merely to offer a few remarks which the consideration of this subject has suggested, regarding the explanation of the manner in which the fetal limbs are occasionally amputated in utero. A number of cases of this description have been collected and commented upon by Dr. Montgomery, of Dublin, and Dr. J. Y. Simpson, of Edinburgh, and the essays of these gentlemen are accompanied by drawings of some of the mutilated parts†. In most instances, evidence is afforded of the presence of bands of organizable lymph, yet neither of these gentlemen suggest that the contraction of these bands might contribute to effect the disjunctions alluded to. It appears to me, however, that such an opinion may be entertained; but when this is maintained, it is at the same time admitted that the growth of the fetus must to a certain extent assist in the disjunctive process, for a band which at first produced no pressure on the encircled limb, would obviously do so as the process of development went on, even supposing that there was no contraction in the band itself. It is therefore suggested, that in this very curious class of cases there are two opposing forces in operation, which, by their opposition to one another, tend to effect an amputation of the part by the same process of disjunctive atrophy which the surgeon accomplishes by means of the ligature.

Though both causes are in operation, the greatest share of the process ought apparently to be ascribed to the contraction of the band of lymph. It cannot be urged that the period of uterine existence is of too brief duration for the organization and subsequent contraction of the effused lymph. The records of fetal pathology, scanty though they unfortunately still are, furnish us with at least one case, which is of itself suffi-

cient to prevent this objection from being urged. Morgagni, on opening the abdomen of a female fetus of the full time, found a quantity of blood effused into this cavity, and upon removing this he saw the viscera buddled together, and enveloped in a dense, tough, white membrane. The lungs were of a brown red colour, and sunk in water. There was no putrefaction*. Now this fetus must have had peritonitis, and the huddling together and atrophy of the abdominal viscera must have been in consequence of the contraction of the false membrane.

Edinburgh, Dec. 1838.

ON THE ABSORPTION OF DEAD BONE.

To the Editor of the Medical Gazette.

SIR,

IN the last volume of the Medico-Chirurgical Transactions is a paper by Mr. Gulliver, the object of which is to prove that dead bone is not absorbed. In this paper†, Mr. G. says "the facts which are brought forward in proof of the absorption of dead bone are simple and easily enumerated—to wit, the gradual disappearance of the sequestrum in many cases of alleged necrosis, the irregular and eroded state of the dead portion, the contact of granulations with the indentations on its surface, the absorption of the fangs of transplanted teeth; and, finally, it has been stated, either on the authority of Mr. Abernethy or Sir W. Blizard, that portions of dead bone had diminished in weight after having been kept in contact with the granulations of ulcers." Mr. Gulliver has shewn that the three first-mentioned facts may be explained without having recourse to the hypothesis of the absorption of dead bone; nor does the absorption of the fangs of the teeth prove the truth of this hypothesis, seeing that living teeth only can be absorbed. Any tooth or part of a tooth, if dead, being exposed to the combined influence of the air, heat, and moisture, will decay, whether it be naturally implanted in the alveolar process, or mechanically maintained in the mouth: according to my observations, the process of decay is

* Dr. Abercrombie mentions several instances in which very slender adhesions were found in fatal cases of ileus; and he supposes that they operated prejudicially, not by producing mechanical obstruction, but by causing "a derangement of the muscular power."

† Dr. Montgomery's papers are in the 1st and 2d, Dr. Simpson's in the 10th volume of the Dublin Medical Journal.

* Epist. Anat. Med. LXVII, Oct. 17, as quoted by Gendrin, Histoire Anat. des Inflammations, tom. I. 269. Paris, 1826.

† Page 3, loc. cit.

alike in both cases. The dead tooth, like dead bone, is not absorbed; but, like living bone, the living tooth is absorbed—an example of which may be cited in the disappearance of the fangs of the deciduous teeth. As the assertion that the surfaces of the discs of bone bound over ulcers were found to be eaten out or destroyed, as in common caries, is in direct opposition to the numerous observations of Mr. G., unless the preparations which form the basis of this assertion can be subjected to the minute scrutiny of one versed in this subject, I should not think that pathologists will feel bound to attach much importance to it. It is evident that these discs of bone were subjected to those influences, the presence of which is requisite for the progress of decomposition; and their diminution in weight, to which Mr. G. has above referred, may be accounted for by the effects of the latter process. Mr. Gulliver, in the last page but one of his paper, says, “these experiments are selected from a great number which I have made, all tending to the same conclusion. They have not been sufficiently varied and extensive to admit of being adduced as a peremptory proof of the impossibility of the absorption of bone, in *opposition to the incontestible power of the absorbents in the removal of inorganic particles from the living body*; but I conceive that it is now fully established with how much difficulty dead bone is subject to absorption, and that whatever may be the agency in the removal of the living parts, it can no longer be regarded as the means by which the sequestrum disappears in necrosis.” I ask for a single proof “of the incontestable power of the absorbents in the removal of inorganic particles.” I do not believe that a single one exists; I have never done so since I read the following passage from Hunter, and carefully examined the grounds he had for coming to the conclusions which he therein draws. “Now the part that is to be absorbed is alive; it must feel its own influence, and admit of absorption; the vessels must have the stimulus of imperfection, as if they were sensible that this part were unfit. There must be a sensation in both parts*.”

In the “Table of Absorption†,” by the same author, no inorganic substance is mentioned: the teeth being considered

as organized; a view which the valuable discovery of Retzius seems more clearly to establish. Mr. Gulliver states that it is generally taught in the schools of London, that dead bone is absorbed. I have shewn that the views of those who make the latter assertion are in opposition to those of John Hunter; the grounds for those views have been enumerated, and it remains for pathologists, who are capable to judge upon this subject, to determine, whether the facts in opposition to these grounds are or are not conclusive. I shall be ready at any time to enter more deeply into this most interesting subject. In conclusion, it is strange that Mr. Gulliver never mentions the name of John Hunter as an experimentalist upon this subject, when the results of Mr. G.’s experiments may be considered as affording a confirmation of those arrived at by that great physiologist. Sir Everard Home*, speaking of Hunter, says, “besides these experiments on the growth of bone, he made others to determine the process of their exfoliation. He cauterized portions of bone in the same way in several different stages of this process, and found that the earthy part of the living bone, in contact with the dead portion, was first absorbed, afterwards the animal mucilage itself, so as to form a groove between the two, which became deeper till the dead bone was entirely detached, the dead portion itself having undergone no change.

PATHOLOGICUS.

OBSERVATIONS

UPON THE

EDIBLE MUSHROOMS OF RUSSIA.

By GEO. LEFEVRE, M.D. &c. &c.

Late Physician to the British Embassy
at St. Petersburg.

I KNOW not what the march of intellect may have done for mushrooms, but they have hitherto held a very subordinate station in the culinary establishments of the British Isles. If botanists have not been ignorant of the nutritious properties of these fungi, they have not gone hand in hand with political economists in imparting their knowledge to the vulgar; hence a numerous tribe has been quite overlooked, or considered

* Hunter's Works, by Palmer, vol. i. p. 255.

† Loc. cit. p. 258.

* Transactions of a Society for Improvement of Medical and Chirurgical Knowledge, vol. ii. p. 277.

as venomous, and one species alone, viz. the champignon, has been separated from a mass of others, which have all been stigmatized by the name of toad-stool.

The child, always eager to lay hands upon what is novel, and prone to taste whatever has the appearance of food, is admonished in its earlier years to forbear touching these profuse productions of nature. Death, made terrible to the being that just begins to live, is threatened as the sure punishment of disobedience. The security of the parent is rendered doubly sure by the choice of nomenclature; for the child, viewing with disgust and terror the poisonous toad, is not inclined to regard with more friendly eye the stool on which it may be disposed to squat. As the infant acquires knowledge by experience, it is taught to separate one species from the mass,—nay some little premium is offered to its industry for collecting that which was formerly forbidden its touch.

How is the child instructed to distinguish the wholesome mushroom from the deadly toad-stool? Does the botanist explain its class and order, its method of reproduction? Does he point out to the little mushroom gatherer the different rugæ under its white, convex, parachute top? No, this would not in the first instance be appreciated by the pupil; but the mother resorts to her own system, and wisely educates the child as she was herself educated. Trusting to the safety of custom and experience she first shews the infant a mushroom. Smell it, taste it, look at it; all of which the child having done, is sent into the woods to procure other specimens. It naturally errs at first; but a few lessons teach it to distinguish the one real from the many spurious sorts, and a month's practice renders it *au fait* of its profession.

Such was long the state of things in England. Vulgar prejudice had pronounced its anathema against all but one individual of the species, and a numerous tribe of edible fungi was neglected and reviled.

Those who have sojourned long in Russia understand these matters better, and turn their knowledge to a profitable account. Two centuries ago our countryman, Dr. Samuel Collins, directed his attention to this subject; and overcoming the prejudices of previous education, adopted the practice of the na-

tives, feeding himself upon all the varieties of this kind of food served at Russian tables. Whether or not he strove to eradicate the prejudice of his own countrymen upon his return to England is not recorded. It often requires more force than one individual may possess to "push men from their stools."

I have ventured to offer a few suggestions upon this subject, which, perhaps, when dilated upon by abler hands, may be the means of adding another flavour to the *fricassé de poulet*, or to the broth of the cottager.

I am indebted to my friend, Dr. Bongard, who has particularly studied this branch of botany, for the subjoined list of edible fungi; and were it generally known how much these productions are appreciated, and how palatable they are, there is little doubt but they would soon become popular, and find a place in the domestic cookery books of England.

It is not a valid objection (though it may naturally arise), that the properties of these fungi may possibly be changed by the severity of the Russian climate. To this it is immediately answered, that the English, upon their return home, after some years' residence in Russia, gather the same species in their native woods, and, to the utter consternation of Betty, the cook, order them to be served at table. John places the dish, with trembling hand, before his mistress, and watches her with fear and trembling. As no harm arises, however, from the feast, John gets bold, and proposes to Betty to dress for their own supper a collection, which he has himself gathered in the woods; the result of which is, that Betty and John are poisoned; for although the champignon is not the only species which may be eaten with impunity, still there are a great many which are highly deleterious. John had not received a Russian education; he had been taught to reason upon the nature of things in general, and not upon any practical application of specific knowledge. Had he been brought up in Russia, he would not have proved himself so destitute of common attainments as to allow himself to be poisoned by so gross a mistake. Should he even recover, it is doubtful whether he will ever be induced, by a second experiment, to rectify his former error.

Still, this prejudice may be conquered, and it requires only a beginning to put the matter in a right train. Now that knowledge is distributed in so wholesale a shape through the medium of tracts and penny magazines, let it not be asserted that the useful and practical is sacrificed to the doubtful and theoretical. Let it not be reproached to the school-master abroad, that he is penny wise and pound foolish. The Russian boor finds the good in every thing; the English peasant knows not how to profit by the stores which nature has spread before him. The child who learns to distinguish the one innocuous from the multitude of pernicious fungi, will, by very little instruction, be taught to separate others from the unwholesome mass, and its knowledge will soon become a profitable source of amusement and occupation.

Grebbee hunting is a regular trade in Russia, and in the autumnal months children flock to the woods to collect these fungi, and sell them at a very remunerating price.

During the long fasts prescribed by the Greek church, mushrooms form an essential part of the food, and are used to flavour the oatmeal and barley broth, and render it more palatable. They are dried in ovens, drilled through the centre, and threaded like beads, much resembling dried artichoke bottoms; and previous to the fasts, "*Grebbees*, *haroski grebbees*?" is one of the cries of St. Petersburg. The vender promenades the streets with strings of them round his neck, and shelves them off in detail at so much per dozen.

In hopes, therefore, that the junior members of the faculty residing in the country, and who are supposed in the present day to be acquainted with botany, may take up this subject, and rescue this part of nature's bounty from those things which are included in "death in the pot," I have subjoined Dr. Bongard's memoir on the edible mushrooms found in Russia.

1. The variety of mushrooms eaten in Russia is not so great as is generally believed. Several species are eaten in France and Germany, which are scarcely made use of in Russia.

2. Many kinds of mushrooms considered to be venomous in other countries are eaten with impunity in Russia.

I.—EDIBLE AGARICI.

1. *Agaricus melleus*, Vahl.

This species has a delicious flavour, and is chiefly used for pies and patties.

2. *Agaricus alutaceus*, Fries.

3. ——— *emeticus*, Schaff.

Both these kinds are eaten in Russia, but the *Ag. emeticus* is considered to be poisonous in other countries. The whole section *Russula* of Fries, in which are included these two species, are much esteemed. The common name of the country implies that they may be eaten raw. They are most palatable when fried in butter. They vary much as to their colour and taste. They are found of a red, of a rose, of a yellow, of a white, and of a violet tint, and of all intermediate shades. Their taste is sweet, acrid, piquant, sometimes bitter; but they are all served at table.

4. *Agaricus adustus*, Persoon.

This kind is but little prized, and is only eaten by the common people.

5. *Agaricus serobiculatis*, Scopoli.

6. ——— *terminosus*, Schaff.

This is considered one of the most dangerous kinds in other countries, but it is very generally eaten in Russia.

7. *Agaricus necator*, Persoon.

Like the preceding, considered poisonous every where but in Russia.

8. *Agaricus trivialis*, Fries.

9. ——— *acris*, Bolton.

10. ——— *retilis*, Weinman.

11. ——— *deliciosus*, L.

Very abundant, and much esteemed.

12. *Agaricus flexuosus*, Fries.

Acrid, but eaten by Russians.

13. *Agaricus piperatus*, Scop.

Considered venomous in other countries, but prized in Russia, particularly when preserved in brine.

14. *Agaricus vellerens*, Fries.

Eatable, as the preceding.

From numbers 6 to 11 inclusive belong to the section *Galorrhoi*, or such as contain a milky juice.

15. *Agaricus involutus*, Batseh.

16. ——— *campestris*, L.

According to this division it is seen that the greater number of *Agarici* which are eaten in Russia belong to the sections of *Galorrhoi* and *Russula*. None belonging to the section *Amanita* are employed as food.

Agaricus muscarius and *vaginatus* are considered venomous, and not used as nutriment.

It has been stated by M. Fries that the *Agar. muscarius* is eaten in Russia (Ru-

thenis edalis.) It is only used to poison flies, as in most countries. In Kamschatka the people prepare an intoxicating drink from this kind; or, if not precisely the same species, at least from one very nearly allied to it.

Agaricus procerus is not eaten in Russia, although it is considered edible in some provinces of France.

Agar. eburneus and prunulus, which are used in other countries, are not eaten in Russia.

17. Cantharellus cibarius, *Fries.*

Generally eaten, but not much esteemed. It has an agreeable odour, but its taste is not equal to its smell.

II.—EDIBLE BOLETI.

1. Boletus luteus, *L.*

2. ——— granulatus, *L.*

These two kinds are much esteemed.

3. Boletus bovinus, *L.* (not common.)

4. ——— variegatus, *Sw.*

5. ——— subtomentosus, *L.*

6. ——— calopus, *Fries.*

7. ——— turidus, *Schaff.*

8. ——— edulis, *Bull.*

9. ——— scaber, *Bull.*

——— {Var. aurantiacus, *Bongard.*

——— {Bolet. aurantiacus, *Bull.*

10. ——— cyanescens, *Fries.*

The genus *Boletus* is used in Russia much as in other countries; but foreigners are afraid of those which turn of a purple colour when cut or broken; as is the case with *bol. turidus* and *cyanescens*. Both these kinds are eaten by Russians with impunity.

POLYPORI.

There is but one edible kind, and that is rare. It is a variety of *polyporus-brumalis*, which springs up in the woods after the trees have been burnt; particularly after the first heavy rain. The common name in Russia, implies that they are produced by fire (*pojarki*). It has not a very fine flavour.

MORELS.

1. Morehella esculenta, *Persoon.*

2. Morehella patula.

3. Hebrella esculenta, *Persoon.*

This species is considered by some botanists as poisonous. It is nevertheless sold in the markets of Petersburg and Moscow, and eaten freely.

3. Hebrella lacunosa, *Apzel.*

TRUFFLES

Are found plentifully in the interior of the empire, but are not so much esteemed as those imported from France.

No species of *Hydnum* or *Clavaria* is eaten in Russia.

ON THE ACTION OF THE RECTI MUSCLES OF THE ABDOMEN.

To the Editor of the Medical Gazette.

SIR,

I HAVE lately been considering the action of the recti abdominis muscles, and the uses of their tendinous intersections. I have also consulted many anatomical works, to ascertain the various opinions entertained upon the subject; none of which, however, appear to me sufficiently satisfactory to explain why these intersections only extend through half the thickness of the muscle, or why the posterior part of the sheath has no adhesion to the muscle, like the anterior part has. These two points have an importance attached to them that I do not think has been sufficiently dwelt upon.

The tendinous intersections are generally three in number, one being situated opposite to the umbilicus, and the other two above it; sometimes there is a fourth, which is then situated below it. The peculiarity of these tendinous bands is, that they do not extend through the whole substance of the muscle, but merely occupy the anterior half of its thickness, leaving the posterior portion of it continuous, from its origin to its insertion. Another peculiarity is, that the anterior portion of the muscle adheres closely to its sheath by means of these transverse bands, while the posterior is unattached, and moves freely upon it.

Meckel says that these tendinous intersections "are undoubtedly incomplete repetitions of the ribs on the walls of the abdomen*;" but upon what analogy and reasoning he makes them such, he does not say. It appears to me that were they so, they should be placed rather upon the sides of the abdomen than upon its anterior part. Others suppose them to give additional power to the muscle, by giving the intermediate portions separate points to act from. But were this the case, why should they not extend through the whole thickness of the muscle? by which they would gain more power still. Another opinion held with regard to their use is, that they allow the muscle to have so many separate contractions,

* Anatomie Descriptive, tom. 2, p. 129.

instead of one large one, which would then press unequally upon the abdominal viscera, but which now is not the case. Finally, Bertin says* that these tendinous intersections do not simply adhere to the anterior part of the sheath, but that they are intimately blended with the fibres of the tendon of the oblique muscle, and that their use is to enable the recti muscles to assist more completely the action of the abdominal muscles than they otherwise could do. He traces some of the fibres upwards, and others downwards, so making them pull both ways upon the oblique muscles. But were this the object of these intersections, we should expect to find them adhering to the posterior part of the sheath as well as to the anterior, for they would then pull regularly upon it, instead of irregularly as they must now do, taking hold of its anterior part.

The explanation I would offer of their use is the following:—The recti muscles of the abdomen are the only ones in the body that have to keep up their tension, at the same time that the direction of their fibres is altered from a straight to a curved line, by which the anterior portion of the muscle is rendered concave, and the posterior convex; for the muscles must take this altered shape before they can have any effect in compressing the viscera, which is their chief office. Now in order to allow of the recti muscles doing this, I believe that their anterior portion, which is rendered concave, should possess a greater power of contracting than the posterior; and this, I think, is gained by means of these tendinous intersections, which we find placed on the anterior part of the muscle only; for I cannot but think that they must increase the power of action in the muscle, and enable it to act with greater energy than the posterior portion, which exists as one long muscle, continuous from its origin to its insertion. This point I would explain by a diagram. Suppose A, B, C, to represent a section of the rectus muscle, with its tendinous bands existing at its anterior part only, in the uncontracted state; and A, D, E, the muscle in action, when it takes its curved shape towards the viscera. Now in order to keep up the true degree of tension, when the muscle takes this altered shape, I

believe that it must contract more at its anterior than posterior part, and more at its most concave part, which is between the umbilicus and ribs; and this is the part where the tendinous intersections are chiefly placed. I am aware that the received opinion is, that these intersections, by dividing the muscle, do not give it any increased power of contracting; but I do not think this can be at all satisfactorily proved, owing to the difficulty of measuring with any degree of exactness the extent of action which takes place in a muscle, and which may be increased or diminished from various causes, which cannot be accounted for by any mechanical laws that are applicable to inert matter.

The other important point to attend to is, the absence of any adhesion between the rectus and the posterior part of its sheath. The object of this I conceive to be, to facilitate the action of the muscle, by allowing its posterior surface, which becomes convex backwards, to play and move freely upon it; which it could not do, were it adherent as it is upon its anterior surface. The tendency then would be, to draw the sheath towards the muscle, instead of pushing backwards, and pressing against the abdomen.

The above explanation appears to me to possess some plausibility, though I cannot say (owing to the difficulty of proving the particular action of different portions of the same muscle) that there

* Mémoires de l'Académie de Paris, 1746, p. 383.

are not objections to it. It is a point, however, of great interest in the physiology of muscular action, and one that I think requires more consideration than has hitherto been paid to it.

I remain, sir,

Your obedient servant,

EDWARD F. LONSDALE,

Demonstrator of Anatomy at Middlesex Hospital.

82, Guildford Street, Russell Square,
Dec. 1838.

publicum sit, dicendi periculum non recuso."

CICERO.

THE WANT OF SUBJECTS FOR DISSECTION.

THE Anatomy Bill, as administered by Dr. James Somerville, was never more inefficient or vexatious than it is this season.

We pointed out last October the evils inseparable from a system of distribution of the bodies, of which the power is placed in the hands of the present Inspector; and they are all now operating with a very greatly increased force. Their existence was, indeed, almost lost sight of during the latter part of the two last seasons; for the metropolis being visited by widely-spreading and destructive epidemics, the supply of subjects could scarcely fail to be sufficient. But even then it was but just sufficient—only just enough to moderate, and at last to lull, the complaints of the teachers, and for a season to secure the Inspector from blame. Up to the present period the metropolis has happily enjoyed the average of healthiness (though not more than the usual average during the autumn and winter months); the supply is extremely deficient; and so long as it shall please Providence to avert the calamities by which we were visited both last year

and the preceding, the study of practical anatomy in London will be little more than nominal.

Let us again shew the absurdity of this scheme of distribution, by which Dr. Somerville is authorized to send a supply of subjects to each school proportioned to the number of its students. Before it came into action, when each teacher obtained what bodies he could, no means were left untried, no interest was unemployed, to persuade the parochial and other authorities to give up the bodies of those who died unclaimed while in their charge. Each teacher then received according to the exertions that he made, or the interest he could move, and every possible source of supply was made available. There was then no lack of subjects, or if there were, it was the fault of the teacher who suffered; and the only complaint was, that the indolent, or those who had the least powerful interest at their command, though well, were not so well supplied as their more active or more fortunate brethren. To remedy this, it was proposed that the supply, then large enough for all, should be equally distributed among them all. And what is the result? Why, that the most influential teachers, finding that they should have to work not for themselves but for their opponents, have given up all their endeavours to increase or maintain the supply. Nor was it likely to be otherwise; for a teacher, by using all the same means which he formerly applied for his own benefit, will now obtain for himself at most one-tenth of the former reward of his exertions. If, for example, he could both then and now obtain ten bodies from any source, instead of receiving them for his own use, they are now to be distributed amongst the different schools; and while he himself receives but a tenth of the proceeds of all his exertions, the remaining nine-

tenths are given to his opponents. It is ridiculous to suppose that any one would work on such terms as these ; and of course no teacher now endeavours to persuade a single parish to permit their unclaimed bodies to be dissected.

But this is not the only evil of the system. Formerly, each teacher was held responsible by the parish or other authorities, for the proper conduct of the dissection, and the decent and punctual burial of the bodies which they consigned to him ; nor would they send subjects to any but those teachers on whom they knew that they could depend for the fulfilment of all that they required in this respect. When, therefore, the system of distribution was adopted, several parishes at once withheld their former supply, the authorities not considering themselves justified in giving up bodies to teachers of whom they knew nothing, and having no confidence whatever in the Inspector, to lead them to think that he would see that the provisions of the Act were duly fulfilled.

But it will be asked, who could be so blind to these, the necessary consequences of such a scheme, as to ask for its establishment? Who could have obtained it? Why, chiefly Dr. James Somerville, who probably wanted a little more importance, and thought he should obtain it by wielding a kind of autocratic power over the teachers, with some of whom he was on no friendly terms. He managed it, by persuading the private teachers, that by joining him and carrying his scheme, they would be placed on an equality with those who, by their connexion with hospitals, had before obtained a disproportionate supply. He thus indirectly raised a great clamour, and so gave the appearance of the additional office of Distributor being forced upon him*.

By this time, however, Dr. James Somerville is, we suspect, the only person who would petition for a continuance of this part of his office ; for if the small schools were formerly supplied in a less proportion than the large ones, they are now not supplied at all. In the general decrease of the whole number of subjects which has made the share of the large schools insufficient, the proportion of the small ones has fallen to 0! and the majority are, for odour's sake, ought to be at this time, empty.

It must be remembered, moreover, that when the Inspector was made Distributor, (the evils which we have mentioned having been anticipated by some of those concerned), he promised to be Purveyor as well, and assured all the teachers that if they would agree to his scheme of distribution, he would take care not only that there should be no diminution of the supply, but that new sources should be opened ;—that all the interest of the government should be employed—and that there should be an actual increase in the number of bodies consigned for dissection. Well, as we have already said, the epidemics of the two last seasons, while they continued, prevented his credit from being attacked ; the supply was just sufficient—the teachers cared little whence or from whom it came—and the purveyor leisurely congratulated himself as he enjoyed the undisturbed ease, which death's unusual doings secured to him. This year, however, the mortality being happily not above the average, it is quite a different thing. The Inspector's part of the supply is now found to be a mere nullity ; and it appears that while the interest of many large parishes has been lost, there has been scarcely one new source of supply discovered.

We will readily grant, that had the right of distributing been bestowed on

* We have only lately become acquainted with

this the true version of the tale, or it should not have remained so long unpublished.

a person possessing more influence or more tact than the present Inspector, it might have succeeded much better; indeed, if the Bill were well worked, the supply would be so abundant that a distribution, or any other absurdity might be grafted upon it, without materially affecting the interests of any of the schools. But with parish authorities, and with nearly all those who have bodies at their disposal, Dr. Somerville is singularly unsuccessful. They, being plain men, can neither understand nor appreciate that air of diplomatic mystery which the Doctor assumes, and seems to think essential to the fulness of official dignity;—they call it all *humbug*. A plain, honest, straightforward conduct is all that would be necessary, not only to conciliate their good will, but to secure their entire co-operation in all that is required; and any man of common respectability, who would pursue this simple course, might insure an efficient working of the Bill.

However, we are less concerned with the detail of Dr. James Somerville's personal defects for this office than with the result, which is, that many sources of supply which were formerly open to teachers of anatomy, are now closed against them. We know the opinions of the officers of several of the parishes; and there are many who say, that rather than have any thing to do with the present "authorities," they will bury their dead poor at their own expense; and many more who, without expressing so much, will yet not give up the bodies, because they know neither for whom nor for what they are destined.

Thus much for the procuring of bodies: the Inspector is, to say the best, useless—private exertion is entirely given up, and a general co-operation of the teachers is, of course, not to be expected. Let us now look to the distribution of the few bodies that come,

as it were, of themselves. After deducting those over which he has no power, viz., those supplied by the hospitals to their own schools, and those from a few parishes who still insist of sending them to the schools which they choose, there is left but a very small number on which the distributor can exercise the functions of his office. For the division of these, which we will assume is equitably managed, there is put in force a machinery most ludicrously ponderous, and at the same time most vexatiously inquisitorial—a registration of the names, place of birth, and place of residence (why not of the parentage, personal appearance, and early habits?) of each student, and a succinct account of his previous anatomical studies, which he has to sign in proof of its correctness, and which the teacher must counter-sign, to certify that the pupil is *bonâ fide* his! Thus the number of students at each school can be guessed at, and the phases of success and failure in each can be shewn to the public in a manner that must be peculiarly gratifying to those whose reputation is on the wane, and with a degree of fairness equal to that which would announce the actual property of each merchant on the Exchange. However, all this confers dignity on the Inspector, which is of much more importance; and, pleading the extraordinary accumulation of these and other similarly valuable documents, he is about to be accommodated with apartments in Somerset House! from which he may inspect, purvey, distribute—and draw his salary.

So much for two parts of the office; let us next see if Dr. Somerville be more efficient in the third—that of inspecting. No; he resides at Chelsea, and scarcely crosses the threshold of any dissecting-room more than twice in the same season; and evasions of the regulations of the Anatomy Bill, which are published in the daily papers, remain unnoticed by him.

In short, the Inspector does not inspect the schools; the purveyor does not obtain subjects; and the distributor has very little to distribute. And now, as this complex official, and his employers, are fond of Returns, we will suggest, as the subjects of the next—the number of new sources of supply which Dr. Somerville has obtained since the scheme of equitable division was commenced; the number that have been withdrawn in the same time; and the number of subjects thus lost. Then let his salary be divided by the number of subjects of which he has had the distribution, that the government may see how much it costs them for each body thus supplied. [We can, without returns, tell them that it is about three pounds]. It might then be well to ask (for Commissioners ask more impertinent questions every day), how much time the Inspector gives to his work? And, in conclusion, it would be but right to consider whether some means might not be found which would prevent the Inspector from requiring the assistance of an annual epidemic to keep him in credit, or to give his office even an appearance of efficiency.

WESTMINSTER HOSPITAL.

CLINICAL LECTURE BY JNO. BURNE, M.D.

November 5th, 1838.

CASE XX.—*Ascites with Utero-gestation; Miscarriage; Ascites cured—Chronic Diarrhea cured by Sesquioxide of Iron and Port Wine.*

IN the two former lectures I offered to your notice various cases of dropsy, and I have yet one more to speak of to day.

Mary Whale, aged 34, married one year, but has had no child, admitted on the 21st of August, 1838. As long as eight years ago she threw up, as she reports, a great quantity of blood, since which she has been in weak health; and latterly subject to a diarrhœa. She did not menstruate till the age of 22, but the periods were al-

ways regular up to last spring. In March her abdomen began to swell at the lower part, and continued to enlarge up to her admission into the hospital. She was of a small stature and delicate frame, exsanguineous, emaciated to a very great degree, and had a sallow linear face, indicative of visceral disease. The abdomen was greatly enlarged, and, on percussion, yielded a very distinct fluctuation; and in the hypogastric region was distinguishable, through the fluid, by the points of the fingers, a hard tumor having an equal surface, as far as could be ascertained. The pulse was small and weak, the appetite indifferent, the tongue clean and reddish, the bowels relaxed, and the urine very scanty, but not albuminous. Diagnosis recorded:—*Ascites*, with a quere as to the tumor being ovarian.

R Potass. Bitartratis, ℥ss.; Tinct. Scillæ, ℥ij.; Sp. Ætheris Nitrici, ℥ss.; Aquæ destillat., ℥vij.; M. 3j. bis quotidie.

On the fourth day after admission she was seized, in the evening, with pain in the abdomen and back; and, next morning, at ten o'clock, she miscarried of a five months' fetus: she herself having no idea of being pregnant until the miscarriage actually occurred.

From this accident she recovered in a few days; after which the ascites gradually increased; but the tumor was gone. The relaxed state of the bowels continued to distress her, and forbade the use of mercury or elaterium; even the bitartrate of potass could not be continued. I therefore had recourse to the endermic use of iodine, in the form of the Ung. Iodinii Comp. rubbed on the abdomen twice a day.

With a view to tranquillize the bowels, kino, opium, and creosote, were severally prescribed, but without effect. The diarrhœa persisted, dejections taking place every quarter of an hour, and exhausting her excessively. I now (Sept. 6) gave her the Ferri Sesquioxidi ʒj. ex Vini Lusitanici ℥j. thrice a day, which relieved the diarrhœa almost immediately, and improved her strength. The iodine ointment to be persisted in.

In the course of a week her health was much recruited; the ascites began to diminish; and, the same means being continued, it had entirely disappeared by the end of September. She persevered in the use of the iron and wine until she left the hospital, on the 9th of October, in comparative good health.

This case, you all, I have no doubt, remember perfectly. It was a combination of ascites with utero-gestation; by no means a common occurrence, although

many cases have at different times been placed on record. In the examination of this patient I at once judged the dropsy to be ascites, for this reason, that the fluctuation was remarkably and equally distinct in every part of the abdomen. In ovarian dropsy, the fluctuation is usually less distinct than in ascites, because the fluid is apt to be thick and viscid, whereas in ascites it is of a more thin and serous nature. A tumor having been discovered in the lower part of the abdomen, the question arose as to its nature, and how far it was concerned with the dropsy. The situation of the tumor evidently referred it to the uterus or the ovaria; but inasmuch as I felt satisfied from the fluctuation that it was a case of ascites, I necessarily paused before determining whether the tumor was ovarian or otherwise; and this point was therefore left for further inquiry.

That a tumor existed there could be no doubt, although at first it was not altogether easy to be distinguished. You will recollect that this patient having a large quantity of fluid in the abdomen, and lying horizontally, there was a considerable depth of fluid between the abdominal parietes and the tumor, so that upon examining the lower part of the abdomen with the flat hand, the tumor was not arrived at. But on making a sudden pressure or dip with the points of the fingers held perpendicularly, the fluid was displaced, and the fingers struck against a resisting body—the tumor. One examination only having been made, and the patient being greatly emaciated, and her face presenting the linear aspect indicative of visceral disease, the idea of pregnancy (in such a person) did not suggest itself; and before my next visit she had miscarried.

This case, as regards the determination of the tumor, is a practical illustration of the manner in which the abdomen should be explored where ascites exists. In the first place, it is necessary that the patient should be in a recumbent posture; for, in the erect position, disease of the abdomen cannot be detected with facility or certainty, the tense abdominal muscles forming an obstacle to the exploration. But when the patient is lying horizontally, with the muscles relaxed, you are able to explore the condition of the abdominal viscera with great exactness. When fluid is present in the abdomen, you determine the co-existence of a tumor more readily and certainly by examining with the fingers held perpendicularly, and making a sudden dip or pressure, than you can do by making pressure with the fingers and hand flat, as was proved in this case. The advantage of this method is also illus-

trated in ascites with enlarged liver, in which case there is generally a considerable layer of fluid between the enlarged liver and the parietes of the abdomen, which prevents you detecting the enlargement of the organ by pressure with the fingers and hand flat; but by making a sudden dip with the fingers held perpendicularly, you displace the fluid, and strike against the solid resisting liver.

You know that the usual cause of ascites is induration of the liver, which, obstructing the circulation through the portal system, causes congestion, and this again the dropsical effusion. It will be remembered that some years ago this patient threw up a great quantity of blood. It is impossible to say whence this blood proceeded, whether from the stomach or from the lungs; but inasmuch as she had abdominal dropsy, and presents, moreover, the aspect of visceral disease, it is probable that the blood came from the stomach in consequence of an indurated state of the liver, although this organ was not enlarged so as to be palpable below the ribs. The disease of the liver, however, was not so decided as to render the ascites permanent; for we have seen that it was removed by means of the compound iodine ointment, aided by the improvement in her strength from the iron and port-wine. The ascites was cured without tapping—a success we can rarely calculate upon.

This case offers, also, a very good instance of the excellent effect of the sesquioxide of iron and port-wine in chronic diarrhœa occurring in shattered constitutions. The patient had a diarrhœa which exhausted her excessively; but, being controlled by the iron and wine, her strength improved, and she was soon restored to a comparative condition of health. In the next case you will further see the value of this remedy in controlling a diarrhœa, which, so far as my experience has gone, yields with difficulty, if at all, to any other.

CASE XXI.—Sub-acute Chronic Hepatitis.—
Enlarged Liver.—Diarrhœa cured by Sesquioxide of Iron and Port-Wine.—Ndes cured by Quinine and Belladonna.

Sarah McCormac, age 23, admitted on the 24th of July, 1838, having been ill 12 months. She was an unfortunate girl, had borne a child before she was 16 years of age, and been the subject of syphilis.

She complained of sickness and vomiting, which had distressed her for three weeks, and of a diarrhœa, which had harassed her for three months previous to her admission into the hospital. She was excessively emaciated, and her life in danger from the exhaustion consequent on the gastro-enteric irritation and diar-

rhea. The abdomen was flat; the liver much enlarged, the right lobe extending as low as the umbilicus, and the left occupying the corresponding half of the epigastric and hypochondriac regions; and the whole was hard and tender when pressed. The dejections disturbed her constantly; were frothy, like yeast; and the quantity voided in 24 hours was large. The tongue was clean; the skin dry and harsh; the pulse small and frequent; no appetite.

R Hydrarg. Chloridi Opii aa. gr. i. M. et in Pilulas viii. divide. Unam secundâ quaquâ horâ devoret. Empl. Cantharidis epigastrio.

July 27.—The calomel and opium quieted the bowels in some degree, but the sickness and vomiting persisted.

R Ammoniac Sesquicarb. Magnesiac Carbonatis aa. ℥ij. Tinct. Calumbæ f. ʒss. Aquæ destillat. f. ʒviiss. M. ʒi. ter quotidie. Rep. Hydrarg. et Opium.

These had the effect, after a few days, of removing the tenderness in the region of the liver, and of appeasing the irritation of the stomach; and, in a less degree, that of the intestinal canal; but she did not make much progress, and the diarrhœa returning, I prescribed, in lieu of the above, *Crocoti gtt. i. ter quotidie.*

Aug. 4.—But little advantage attended the use of this medicine; it was therefore discontinued, and the *Ferri Sesquioxidi ʒi. Vini Lusitanici f. ʒi.* substituted.

In the course of two days she began to experience decided relief from the iron and wine; and in five or six the bowels became steady, "felt comfortable," the dejections being reduced to two or three in the twenty-four hours; the appetite returned, and she soon began to gain flesh.

20th.—Being now very much better in every respect, the iron and wine were discontinued, and an effort was made to reduce the enlarged liver by means of iodine, beginning with small doses, guarded with opium.

R Potassii Iodidi, ʒj.; Potassæ Bicarb. ʒij.; Tinct. Camph. Comp. f. ʒiii.; Aquæ destillatæ, f. ʒviiss. M. ʒj. ter quotidie.

This remedy was persevered in, with occasional interruptions, for a week, when a relapse of the diarrhœa occurred with so much violence as to oblige me to abandon the iodine, and to resort again to the iron and wine. These had the same beneficial influence as before, and under their continued use she gained flesh and strength daily (the liver, nevertheless, remaining as large as usual,) and was about to be dis-

charged from the hospital, when, towards the end of September, large nodes appeared on both tibiæ and both ulnæ, accompanied with severe pain, heat, and tenderness.

On account of the irritable state of the alimentary canal, the internal exhibition of iodine or mercury was out of the question. I therefore directed the *Ung. Iodinii Comp.* to be applied to the nodes; but this having proved too irritating, recourse was had to the following:—

R Potassii Iodidi ʒj.; Adipis ʒj. M. f. Linim. partibus affectis admovendum.

R Quinæ Disulph. gr. v.; Extracti Belladonnæ, gr. j. M. f. Pil. ii. bis quotidie sumend.

All agreed well except the belladonna, which produced vertigo, dimness of sight, and heat and suffusion of the face, on which account the dose was reduced to a *quarter of a grain*, which was borne without any unpleasant effect. Under this treatment the pain, heat, and tenderness of the nodes began to subside quickly, and the nodes themselves to recede; but, desirous of determining on which remedy the curative effect depended, I desired the patient to discontinue the use of the iodine and to persevere in the quinine and belladonna. With these remedies (the iodine having been omitted) she progressed rapidly, the nodes diminished from day to day, and she left the hospital convalescent in the course of a very short time, having gained more flesh than one would suppose it possible, under the circumstances of so large and so diseased a liver.

This was a very well marked example of subacute-chronic inflammation of the liver, with enlargement of the organ, depending, no doubt, on the irregularities of the individual, she having been "on the town," and guilty of the excesses which most of these unfortunate persons fall into.

By subacute-chronic inflammation is meant inflammation—*mild* as regards degree, but *long* as regards duration: it was a subacute inflammation, lasting a considerable time, and therefore chronic also. In this patient the enlargement of the liver was well defined; and the outline which determined its size was traced with less difficulty than in most other cases, because the abdomen was flat, from the emaciation and diarrhœa: one could distinctly mark the diseased organ extending as low as the umbilicus.

Where the liver is enlarged, and the abdomen distended with flatus at the same time, the exact size of the viscera is not so easily distinguished. Under these circumstances you may avail yourself of the plessimeter, which will indicate the

dimensions of the liver by the dull sound emitted when the plessimeter is struck; whereas, when you pass the boundary of the solid liver, the sound will be hollow, owing to the flatus in the intestines, so that by these signs the extent of an enlarged liver may be defined exactly. In the case of McCormac it was unnecessary to have recourse to the plessimeter, on account of her emaciated condition.

The irritability of the stomach amounted almost to a muco-gastritis, and depended, in a great degree, on sympathy with the liver; for wherever there is hepatitis, acute or subacute, of the parenchymatous substance of the liver, there the abdominal viscera, as the stomach and alimentary canal, will sympathize more or less: but where there is sero-hepatitis, or inflammation of the peritoneal surface of the liver, then the thoracic viscera will sympathize, as evidenced by the cough and trouble in the respiration which always accompany this inflammation. We have in the hospital, at the present time, a well marked instance of sero-hepatitis, in which this sympathy of the thoracic viscera exists, and which case I shall bring forward on a future occasion.

All these cases of sub-acute hepatitis, with great gastric irritation, occurring in constitutions shattered by intemperance, are difficult to cure, so constantly does the stomach reject all medicine. That which I find most useful to commence with is calomel and opium, the dose being small in proportion to the irritability of the stomach. I gave this patient only the eighth of a grain of each, which agreed well, and produced a beneficial effect. I remember prescribing for a gentleman, under such circumstances, the twelfth only of a grain of calomel, and the same quantity of opium, with great advantage. Medicines, therefore, in these minute quantities, are more beneficial in an irritable state of the stomach, than when prescribed in what are called decided doses.

I have no doubt, also, that the cure was aided by the regimen the patient was obliged to observe in the hospital, which insured abstinence from spirituous and other fermented liquors, which persons accustomed to such stimulants will not observe, if left to their own discretion, however great their sufferings. When the inflammatory symptoms had in some degree subsided, recourse was had to the ammonia, magnesia, and calumba, a combination which will frequently appease the irritability of the stomach at this time.

When this patient first came into the hospital the diarrhoea was most urgent; she was worn down and exhausted by the constant action of the bowels, for although

it was more or less checked by the calomel, opium, &c., yet it returned constantly till I had recourse to the iron and port-wine, which, proving signally efficacious, arrested the diarrhoea, and greatly improved her general health.

The appearance of the nodes was extremely sudden. She was on the point of leaving the hospital, when she exhibited large nodes on both the tibiae and both the ulnae, saying they had formed since my last visit. They were hot, rather red, and severely painful; and might have been suspected to be syphilitic. This would necessarily have suggested the use of mercury or iodine—remedies which, in the irritable condition of the alimentary canal, it was impossible to think of resorting to, except the latter endermically. I had seen nodes on former occasions, depending simply on a cachectic state of the system, wherefore I thought it advisable to have recourse to medicines calculated to assuage pain and improve the general health; both which objects were attained by the quinine and belladonna.

When belladonna is given in too large a dose, it is said to produce heat and efflorescence of the face and surface of the body, vertigo, and dimness of sight, all of which signs appeared in McCormac. It is on account of this power of belladonna to produce efflorescence, that Hahnemann, the homœopathist, fixed upon it as a remedy in scarlet fever; and undoubtedly a most efficacious remedy belladonna is in that fever, but not in an infinitesimal dose, as I believe.

The belladonna having produced so much effect, it became necessary to diminish the dose; which being thence reduced to a quarter of a grain, agreed well, and in conjunction with the quinine cured the nodes.

In the administration of powerful medicines like belladonna, it is necessary to be circumspect, and to watch their effects closely. Belladonna is a valuable remedy when the dose is regulated with due precaution; but otherwise, results of an unpleasant nature may arise.

Nodes are said to depend on inflammation of the periosteum, accompanied with more or less swelling of the bone: the inflammation of the periosteum being the primary condition. We have lately had two examples (one still in the hospital) of inflammation of the bone itself, which, having some affinity to the case of nodes, may be now briefly spoken of.

Of the cases to which I allude, one occurred in a young man admitted on account of rheumatic pains. On examination, however, it was found that the pain of which he chiefly complained was si-

tuated in the left thigh-bone, and that the bone itself was much enlarged from below the great trochanter to near the condyles, and the limb so weak as to require him to use a crutch. On the outer side of the knee there was also a small fistulous abscess. From the history given by the patient there remained no doubt in my mind that rheumatic inflammation had settled in the bone of the thigh, and produced necrosis, as will be apparent.

The fistulous abscess had a small orifice, and when a probe was inserted, in order to determine whether any sequestra could be felt, none was perceived; and you may remember that the matter discharged from the abscess had not the fetid odour of a carious bone. But these seem to be peculiarities of this stage of necrosis. Mr. Russell, who published a "Practical Essay on Necrosis," says, "The matter which discharges from these fistulæ is almost uniformly of a good quality, neither offending in point of smell, colour, nor consistency." He also mentions, that "a probe introduced at the orifice of the fistula, seldom penetrates to any great depth, or discovers any loose piece of bone; for in this stage the sequestra can seldom be felt." The probability, then, is, that the bone was already dead, and that the enlargement depended on the osseous shell which forms in necrosis.

The other case, at present in the house, is that of George Milton, aged 42, who was also admitted on account of rheumatic pains. In him the left thigh-bone is enlarged, with pain shooting from the hip to the knee, much aggravated when he is warm in bed. He feels the limb weak, and walks rather lame, but there is no abscess, and the swollen bone does not feel so hard as in the former patient. He has had gonorrhœa more than once, but affirms that he has never been affected with sores—that he has never had syphilis.

From the condition of the bone, and other symptoms, it is evident that the enlargement is the result of inflammation of the bone itself—ostitis; and if it does not yield to treatment, there is danger of necrosis. The plan adopted has been counter-irritation over the whole thigh, by croton oil, purgatives, warm baths, and moderate diet; abstinence from all kinds of fermented liquors.

Necrosis is seated in the long bones: it seldom or never occurs in the flat bones, except the lower jaw, where it is generally the result of an injury. These efforts have been followed by a certain diminution in the general size of the bone, and some relief to the pain, but he is still weak and lame.

I advert to these cases in order to intro-

duce one practical observation. Necrosis belongs to the department of surgery, but inasmuch as inflammation of the bone, which may lead to necrosis, may arise while the patient is under the care of the physician for rheumatism, I wish to excite your attention, and to render you alive to the first signs of any such disease, because it is in the commencement only that treatment will avail. Unless the case is understood, and proper measures are adopted, even before the bone has swollen, the chance of saving it from necrosis is, according to the evidence of Mr. Russell, very slight. If, then, a patient under care for rheumatism is attacked with severe pain fixed in one of the long bones, you would suspect inflammation of that bone; and the pain persisting, you would have recourse to antiphlogistic measures, in order to resist and subdue the inflammation. If the cause of this pain is not understood, the nature of the disease will not be discovered till enlargement of the bone has taken place, and the second stage, in which necrosis will probably form, is at hand. This is the practical point which I am desirous of impressing upon you.

It is the characteristic peculiarity of rheumatism to shift from place to place—not to fix itself in one part or about one articulation; one part gets well, and another becomes affected: rheumatic inflammation is erratic. Hence, if you find one joint remains more permanently affected—if the symptoms of pain, heat, &c. seem more localized than usual, you will be alive to this circumstance—that probably the rheumatic inflammation is no longer confined to the tissues external to the joint, but that it has absolutely invaded the synovial membrane, and you will adopt means accordingly—that is to say, you will direct your remedies to this joint; whereas, so long as rheumatism wanders from one joint to another, so long you are sure that no important tissue is concerned, and that the disease will yield in due time without permanent injury to the articulations. So if the pain should manifest itself in one of the long bones, you would be aware of its importance, and treat it accordingly.

There are now several cases of great interest on both sides of the house. It is worthy of observation, that although for several weeks, I might almost say months, we have been without much active disease, yet immediately that the weather changed, and we had humidity with cold, the wards became full of serious organic inflammations, which will pass under our review in due time.

WESTMINSTER MEDICAL
SOCIETY.

December 1, 1888.

DR. CHOWNE, PRESIDENT, IN THE CHAIR.

*Discussion on Delirium Tremens—Poisoning by
Carbonic Acid Gas.*

A MEMBER asking a question as to the greatest quantity of opium that could be given safely,

Dr. Addison stated that he concurred in the general opinion as to the efficacy of the salts of morphia in certain kinds of delirium tremens. He thought the term *delirium tremens*, adopted as a name for this singular disease, objectionable, because in many cases tremor did not prevail; and in others, where there was a highly irritable constitution, this tremor (supposed erroneously to be proper to this disease) might accompany and precede attacks of apoplexy and hemiplegia. He had witnessed several cases of this nature. In such circumstances bleeding and a vigorous antiphlogistic plan of treatment, were indicated. But in the true delirium tremens, bleeding was not always proper; but there were instances in which, in his opinion, the depleting system was indispensable, but great vigilance was required of the medical attendant, in order to ascertain the capricious variation of the symptoms, and alter his remedies in consequence. He was of opinion that delirium tremens did not always arise from excess in drinking; it sometimes was a consequence of moral causes. One case especially presented itself to his recollection; it was but one amongst many that he had witnessed. A young woman of respectable station became the housekeeper of an aged relative. She grew attached to a nephew of her employer; but this gentleman discouraged the intercourse between the young people, and, to put a final stop to the affair, he sent her back to her friends. She soon became affected with the well-known symptoms of delirium tremens; but no remedies availed, neither ordinary stimulants, nor opium in any shape, nor depletion, produced the slightest benefit. He, Dr. Addison, was disposed to think that there was an important distinction between the delirium tremens arising from moral causes, and that arising from sensual intemperance, though the line of demarcation had not yet been well drawn. In the former class of maladies the treatment was much less successful than in the latter. He thought medical men would find this to be a productive field of investigation.

Mr. Streeter would inquire of Dr. Addi-

son whether he had not experienced that cases arising from sudden breach of drinking habits were not of a much more obstinate kind than those arising from an uninterrupted continuance in the potational intemperance. Such was the conclusion to which his experience had brought him. He would also inquire of Dr. Addison what he had found the pathological condition of the brain to be in cases of delirium tremens generally. In two instances which had occurred to himself he had, by a post-mortem autopsy, ascertained the presence of serous fluid in the ventricles, and between the surfaces of the arachnoid. He had seldom seen any great degree of injection of the blood-vessels of the encephalon.

Dr. Addison acknowledged there was an idea prevalent that cases of delirium tremens springing from sudden abstinence were more intractable than others, but he was not yet prepared to yield his full assent to the proposition. In the pure cases of delirium tremens which he had had the fortune to witness, he could not trace any marks of inflammation in the brain; he had frequently observed a greater whiteness than usual in that important viscus. He had heard Sir Astley Cooper declare that such also was the result of his experience. In some instances he (Dr. A.) had seen slight opacity of the arachnoid membrane, and patches of lymph underneath it. He had but seldom observed the brain to be injected. He reiterated his opinion that many cases are named delirium tremens which were true examples of apoplexy in nervous temperaments, and in which extravasation of blood or effusion of serum would be found in the cavities or around the periphery of that organ.

Dr. J. Johnson thought that cases of delirium tremens arising from mental causes could not be unknown to practitioners who conjoined the talent of observation to the possession of experience. He had recently attended a medical man of great accomplishments, in whom *love* was the cause of the malady; but what was singular in the history was, that the "lady love," who attended the gentleman most assiduously during his illness, became, upon his recovery, affected with the same disease. The ordinary treatment with opium proved effective in both cases.

Dr. A. T. Thomson had seen a case in which a young gentleman, reared up as the heir to a large estate, being disappointed of his inheritance, became the subject of this disease. He (Dr. T.) was disposed to think that peculiarity of temperament had a great deal to do with the liability of individuals to be attacked with delirium tremens. The sisters of his pa-

tient were martyrs to hysteria, and he felt disposed to believe that there was some kindred between the two affections.

Dr. Johnson said that his patient was of a nervous temperament, and it might be possible that that might be a predisposing cause.

Mr. C. Chowne related the case of a medical student, who, having read a good deal upon the maladies of the urinary organs, became the subject of delirium tremens, and fancied that he had a stone in his bladder. He was treated with opium and stimulants, and recovered.

Dr. Addison was inclined to consider the case of Mr. Chowne as one of monomania. He certainly thought that the pathological condition called delirium tremens was due rather to irritation than inflammation of the brain.

Mr. Snow inquired of Dr. Golding Bird whether, in the statement he had made to the Society on a previous evening, viz., that from eight to ten per cent. of carbonic acid in the atmosphere would be fatal to life, he meant simply an adulteration of the atmosphere by the admixture of that quantity of carbonic acid, or the deterioration of the atmosphere by decomposition, so as to produce that proportion of carbonic acid in it, as in a brewer's vat, or in a chamber where the burning of a charcoal stove had occurred.

Dr. Bird replied that his opinion was derived from certain experiments performed by Müller, as well as experiments conducted by himself. He thought that an atmosphere impregnated with that quantity of carbonic acid would be fatal to life.

Mr. Snow now made some observations in a very low tone, and consequently his meaning could not be very well caught. He stated that an important difference existed between the two cases, although the fact had not been noticed by any writers. Death did not arise in either case from the sedative power of the carbonic acid gas, but from the deficient quantities of oxygen in the atmosphere. The lungs could only extract a certain volume of oxygen from the air, in consequence of the affinity which one gas bore to another. When an atmosphere is deteriorated by respiration, by a charcoal stove, or by any other chemical process, the proportion of the constituent gases is very different from what it would be in the case of a simple adulteration of the atmosphere by the addition of 10 per cent. of the deleterious gas, for the process of combustion not only adds carbonic acid to the atmosphere, but abstracts a large portion of its oxygen, and thus in three ways renders it unfit for respiration: 1, by adding a quantity of

carbonic acid; 2, by abstracting from the wholesome proportion of oxygen; and 3, by setting free another deleterious gas, the nitrogen. '017 of carbonic acid gas generated by the burning of charcoal, would be equally destructive with '68 of the same gas introduced by simple mixture. Mr. Snow had mixed certain gases, and had respired with impunity as much as '40 of carbonic acid, when the proportion of oxygen was increased in an equal degree; and he inferred, from his experiments, that the absence of oxygen, not the presence of carbonic acid, or any other gas, was the usual cause of death in cases of asphyxia from deteriorated atmosphere.

Dr. Bird thought the physiological effects of the carbonic acid would be the same, when the proportion of the gas in a given atmosphere was similar, whether the gas was added to the atmosphere, or the atmosphere was deprived of part of its oxygen by the combustion of charcoal. The observation of Mr. Snow, touching the emancipation of the nitrogen, he thought interesting, and had a practical application; for if in a chamber containing 110,000 cubic feet of respiratory atmosphere, 49 pounds of charcoal were burnt in ten or twelve hours, not only would 1500 cubic feet of oxygen be absorbed, but 9,000 cubic feet of irrespirable nitrogen would be set free, and thus two poisonous gases would at one time exert their influence upon the living frame of the inmates.

Dr. A. T. Thomson considered that it would be interesting to measure the sedative and suffocative influence of the carbonic acid gas. In some cases death was produced gradually by apoplexy from the absorption of this gas, by the lungs of a person lying near a stove. When an animal was suddenly placed in an atmosphere containing this gas, the glottis closed, and death from suffocation occurred. Dr. Priestley had proved the sedative property of carbonic acid, for having burnt his hand, its immersion in a jar of carbonic acid immediately relieved him.

Professor Everitt thought it important to ascertain how much less than '10 of carbonic acid in the atmosphere could for a length of time be inhaled with impunity. It was admitted by the several proprietors of the various stoves, that by the combustion carried on in them, one per cent. of the deleterious gas was added to the atmosphere. How long could such an adulterated atmosphere be respired without danger or injury. For his part, he should not like to breathe in such a medium, especially when he recollected the result of the experiments of Saussure, who was the greatest chemical authority on the subject. That eminent philosopher

had made many thousand experiments on atmospheric air, taken from high and low situations, at all seasons of the year, at all times of the day and night; in crowded assemblies and in the open plain, and in short under every variety of circumstances, and the maximum of carbonic acid obtained in any case was '0004. The one per cent. of carbonic acid introduced in the atmosphere of air by the combustion carried on in these stoves was twenty-five times in amount what the natural state of the air contained. It was for medical gentlemen to decide what the effect upon health of the habitual use of such an apparatus would be. Some people, he had observed, were peculiarly sensible of the presence of the gas; and a very slight increase of what might be called its normal proportion, caused disagreeable symptoms.

Dr. Bird would bear his testimony as to the different susceptibility of individuals to the influence of carbonic acid gas. He had notes of three instances which proved the truth of Mr. Everitt's observations. 1. Two sisters, in Paris, slept together in a room where was charcoal burning in a chafing-dish. One sister slept with impunity, but in the morning she found her sister dead by her side. 2. In a second instance, related to him by Mr. John Read, the mechanician, a young woman, with her husband and her child (very young), slept in a room where burning charcoal was put in the fire-place. The husband, on rising in the morning, found his wife dead and his child insensible. 3. The third instance was that of two medical students in a dispensary, who, in cold weather, burnt charcoal in a warming-pan, to keep them warm. In a short time one of them fell down senseless; the other remained unaffected.

Mr. Everitt supposed that every body was familiar with the inconvenience experienced from the use of the stoves in Germany. In that country the fire was not in the room, and consequently the inconvenience was not the effect of any deterioration of air. It arose from the great dryness produced by the want of circulation of air, and the consequently greatly increased evaporation from the surface of the body. In his opinion, it was a chemical law that all gases had a strong tendency to intermingle, and would do so in a given time. Carbonic acid evolved from a brewer's vat, or from a stove, would soon diffuse itself in the atmosphere of a room. The gas given off from a stove being of a higher temperature than the surrounding air, would ascend; but the motion of the air would soon cause it to mix equally. There would be no more danger near the stove than away from it.

Dr. Bird agreed with Mr. Everitt that

the admixture of gases in a small apartment would quickly take place, and the specifically lighter gas would ascend, as in the case of the heated carbonic acid; but it would only ascend until it had disengaged itself of its caloric, when it would rapidly descend. But in the immediate neighbourhood of the stove the stratum of air would be heated, and its specific gravity so much diminished that the newly generated carbonic acid would at once intermix with it. In fact, in the large stove in St. Michael's church, Cornhill, a stream of carbonic acid could be ascertained to be descending from a hole in the side in a parabola to the ground. He thought the objection obtained equally against Dr. Arnott's stove as against any other.

To prevent the dryness of the atmosphere produced by these stoves, he recommended a wet sponge to be placed in a flat dish, with a perforated cover. From this a constant evaporation would be kept up.

IDIOS.

ERRATA.—In the last report, p. 381, l. 10 from the bottom, for "carbonic" read "caloric;" p. 382, l. 11 from the top, for "water" read "lime-water."

PHYSICAL SOCIETY, GUY'S HOSPITAL.

December 1st, 1835.

DR. BARLOW IN THE CHAIR.

Case illustrating the injurious Effects of Joyce's Stoves.—Paper by Dr. Ashwell, and Discussion on the morbid Effects of protracted Lactation.

WHEN the minutes of the preceding meeting had been read and confirmed,

Mr. Chapman, of Tooting, related the following case illustrative of the prejudicial effects of Joyce's stoves:—

CASE.—On the 15th November of the present year I received a hasty summons to attend Mr. W. J., æt. 19, and found him in the semirecumbent posture, labouring the following severe symptoms, viz.:—Violent pain in the head, with a sensation of constriction around the forehead and temples, resembling (as he said) that produced by a tightly bound cord; widely dilated pupils, feebly contracting when exposed to light; singing in the ears; pulse 120, feeble and regular; great paleness of the face, with slight lividity of the lips; extremities cold; hands of a faint purple hue; slightly difficult and irregular respiration; and prostration of strength amounting to inability to stand.

Hot water was applied to the feet, and a small quantity of brandy and water and

ammonia was exhibited, with the effect of gradually increasing the volume of the pulse, and restoring warmth to the extremities.

Though the amount of stimulus was but small, he became very violent, endeavouring to thrust away those around him; and the pain in the head still continued without diminution. About 6 ounces of blood were then taken from the arm, with the effect of relieving his head symptoms, increasing the activity of the pupils, and diminishing the difficulty of breathing. About an hour after the abstraction of blood, he became calm and collected, and gave the following history of the cause of his symptoms:—

He stated that he was perfectly well after breakfast, and that he retired to study in a small room warmed by one of Joyce's stoves. Within an hour he felt a little pain in the head, and dizziness, which obliged him to open the window, when these disagreeable sensations vanished; but, feeling the cold air uncomfortable, he was induced to close the window, and remained at his studies for another hour, when he felt so seriously indisposed, that he was compelled to leave the apartment. His friends, alarmed at his aspect, immediately summoned me to his assistance, and the above-mentioned symptoms were then carefully noted.

No discussion arising upon this case,

Dr. Ashwell read a paper on the morbid effects of undue lactation.

This was a subject of great importance, and it was surprising that so little had been written upon it; for, with the exception of Dr. Marshall Hall, who had alluded to some of the derangements of the nervous system associated with suckling, he was not acquainted with any author who had said much about it. There were three positions which he was desirous of maintaining in the present paper:—1st, Lactation to be morbid need not be of long continuance, a few weeks being often sufficient to induce mischief. 2d, This mischief is not always merely functional, for organic disease occasionally results from undue lactation. 3d, Weaning is the principal efficient remedy. With regard to the symptoms and effects alluded to, he would make this general remark, that however they may vary in degree, or be modified by accidental concomitants, "still exhaustion is the permanent morbid state associated with undue suckling." The following is the usual order in which the symptoms proceed:—Women of a weakly constitution, who have been chlorotic or out of health before marriage, are most liable to suffer. An imperfect nourishment of the infant, and the general debility, anæmia, and pallor of the mother, indicate that the evils of over-lactation

have commenced. Inquire closely, and it will be found that the milk is scanty, with difficulty secreted, and at long intervals, so that the child is obliged to have a supply of artificial food. If the attempt to nurse be persisted in, these effects become more apparent. Together with general mental excitement there is a frequent proneness to hysteria; the pulse is rapid and weak; the muscular system throughout relaxed and enfeebled; appetite gone, or capricious; bowels constipated and flatulent, or painful and relaxed; there is headache, giddiness, impaired vision, and almost always pain between the shoulders, and below the cartilages of the false ribs. Now succeed swelling of the face and ankles, dyspœa, palpitation, short hacking cough. Sometimes the uterus sympathizes, and there is menorrhagia or leucorrhœa present. So far all is merely functional and remediable; but if these be allowed to go on, "organic changes in the brain and lungs, and perhaps in the other viscera, are occasionally resulting from undue suckling."

Our limits do not permit us to give more than this imperfect summary of the Doctor's highly-interesting paper; suffice it therefore to say, that he illustrated each of his positions by the narration of a case. The first, that of a woman in whom phthisis appeared to be the direct consequence of protracted lactation. The second that of a lady, who became the subject of mania from the same cause, and which afterwards terminated in recovery; (the Doctor has never seen *permanent mania* arising from suckling.) And third, a case where, in consequence of lengthened and undue lactation, epileptic fits and convulsions supervened, which at length terminated in fifteen months in death. On post mortem examination, three or four softened tubercular bodies were discovered within the brain, &c. &c. This case Dr. Ashwell had traced from the commencement, and believed that its fatal result was clearly attributable to the nursing.

Mr. Hiff remarked, that all the organic lesions mentioned by Dr. Ashwell might arise from other causes totally unconnected with lactation; on the other hand, lactation was often continued for a remarkably long period without injury: thus, a woman suckled her own child for sixteen months, and then took her sister's for six or eight months longer, with impunity. He could testify to the fact of a woman, fifty years of age, who, at the cessation of the catamenial epoch, being separated from her husband, and having borne no child for twenty-three years, had a full breast of milk. He had mentioned this case to Dr. Blundell, who had told him of another like it. There was also a record of a

negress who had suckled her grand-child.

Dr. Loeck said, a still more extraordinary case than any of these was related in obstetric works: it was that of a woman at Asbby-de-la-Zouche, who had continued unceasingly to suckle children till she was seventy years of age. Unimpregnated women had been known to give milk; and in Captain Franklin's voyage to the North Pole, a male was stated to have performed this function.

He coincided with Dr. Ashwell, that time had nothing to do in producing morbid symptoms in nurses, for it was no uncommon thing for a wet-nurse to suckle a child eight or nine months, then go home and hire a younger child, and suckle a second infant in a new situation. He had known this happen a third time, and the third infant was quite as healthy and hearty as the first. Dr. Loeck had never known organic disease to originate from over-lactation; he had seen phthisis co-exist with it, but not produced by it. Functional mania, however, he had often seen, and he was inclined, with Dr. Gooch, to think there was some peculiar connexion between the brain and uterine system, independent of simple debility, whereby derangements in the latter produced symptoms in the former. This mental derangement was too frequently mistreated by friends, who are apt to recommend amusement and excitement as a diversion for its relief; but this only induces further depression, and aggravates all the symptoms. He had found quiet without excitement, freedom from every care, attention to the general health, tonics, sedatives at night, *no* stimulants, to be the best treatment of this mania. He had not seen organic disease in the brain from lactation. With regard to the lungs, a high authority (Sir James Clarke) was in the habit of advising moderate suckling in delicate women, in whom consumption was apprehended, as a means of diverting the disease, and in many cases under his own knowledge, obvious benefit had resulted. He would ask Dr. Ashwell how far he could undertake to pronounce that organic lesions ever resulted from suckling?

And Mr. Field wished to be informed whether depletory measures were ever advisable, and under what circumstances, in these maniacal affections?

Mr. Hilton also appeared to doubt that organic disease originated in undue lactation.

Dr. Ashwell fully agreed with the greater part of Dr. Loeck's observations, which, indeed, were in complete accordance with his own paper; but with regard to Sir James Clark's recommenda-

tion, he did not think the case analogous. No doubt, where inflammatory excitement prevails, and pulmonary irritation exists, moderate suckling might operate beneficially as a counter-irritant; but where tubercles existed, he was apprehensive and believed that nursing tended to call these into action, and to soften them prematurely. Pregnancy retarded, but lactation promoted the progress of pulmonary tubercular disease. He would not go so far as to assert that suckling could absolutely generate tubercles and other malignant forms of disease; but where they pre-existed, or there was a tendency to their production, suckling too often acted as the immediate existing cause of calling them into active operation. In answer to Mr. Field's inquiry, he said he had never yet met with a case where he had bled; he had occasionally cupped or leeches; but he could imagine that lactation might now and then give rise to symptoms of so active a character as to justify depletion from the arm. He had seen very few cases of puerperal mania that bore bleeding; he had known two such to die; the one was bled lavishly at first, and never rallied; the other was mistaken for phrenitis, and being repeatedly depleted, died. Both in his paper and in his subsequent remarks, Dr. Ashwell drew particular attention to the analogy in the general character and symptoms of the mania arising from over-lactation, and that mental derangement of the lying in state, called puerperal mania, each of which occurred in the same kind of constitution, exhibited analogous features, and required to be treated upon the same general principle of treatment.

Mr. Holdham having understood, from the discussion to night, that the exhaustion produced by lactation was, in points, different from simple debility, would be happy to hear some further remarks in illustration or explanation; and

Mr. Haygarth quoted Andral, who says that lesions of the cerebellum, particularly of the vermiform process, were associated with derangements in the uterine functions.

Dr. Loeck had observed, that puerperal mania exhibited a strong analogy to the cerebral symptoms to which he had already referred, as arising from undue lactation; but there was one feature of singularity, viz.—Puerperal mania might exist altogether independent of exhaustion, and without any cause tending to promote exhaustion, whereas the mania of over-lactation never came on until exhaustion had been first induced by suckling; yet there was a resemblance in the general character and nature of the delirium, and both seemed to require similar principles

of treatment. The patient cannot bear to be troubled about trifles, or to be teased about the simplest arrangements of her daily pursuits; the temper is not morbidly deranged so as to demand either seclusion on the one hand, or excitement on the other; but it exhibits more of the caprice and waywardness of hysteria, and she requires to be kept perfectly relaxed and free from care. His remedial measures are:—1. weaning; 2. change of air and scene; 3. narcotics at night, for undisturbed sleep is of essential importance; 4. mild tonics during the day. The tincture of hops he considers peculiarly efficacious in these cases as a bitter tonic and sedative. As far as his own observation extends, the bowels are usually natural; if otherwise, he does not think this mania is much influenced by it. He does not think the pulse is quickened or excited; it is irritable and excitable, but when at rest it is quiet. When he finds it permanently excited, he apprehends the existence of organic action some where, but prior to and independent of the suckling. He had never seen mania of this kind which did not eventually subside, and had no personal experience of the state of the cerebellum in these maniacal affections. With regard to puerperal fever, too, his experience went to shew that depletion was mischievous, even a few leeches being capable of doing much harm. Purgatives, sedatives, repose of mind, constitute the remedies upon which he relies. In these observations of course he did not mean to include cases where phrenitis or other complication existed, where depletion was most clearly indicated.

Mr. Greenwood supposed, that although the symptoms might be the same in puerperal mania, and in mania from undue suckling, yet as the former was independent of exhaustion, and the latter always accompanied by exhaustion, the treatment in the two cases might occasionally be different also. He thought it important in overlactation to attend to the bowels before exhibiting the tonics and sedatives recommended by Dr. Loeck. He agreed there was a peculiar sympathy between the brain and the generative functions; and he regretted that the refinements (so called) of society had appeared to exercise so baneful an influence on the sex, that very few women in the higher ranks of life were in a fit state of health or constitution properly to discharge the duty of mothers in nursing their own offspring.

The society's time of adjournment being past, Mr. Chapinan and Mr. Iliff proposed a vote of thanks to Dr. Ashwell for his communication, and the meeting separated.

SCHOOL CERTIFICATES.

To the Editor of the Medical Gazette.

SIR,

IN your leading article in the GAZETTE of Saturday, the 24th November, you observe—"at a real school we take it for granted that some method would be adopted, if not of compelling the attendance of students, at least of noting the absent." But, what if such a method is not adopted at any one of the numerous so-called schools, with which London is overstocked? I fear the inference is too just, namely, that there is no real medical school in London. While our medical legislators have been making their calculations as to the maximum and minimum of lectures to be given on certain subjects, it seems never to have occurred to them that it was possible students might be ill taught, or even not taught at all, although 100 lectures had been given. All the laws seem to be stringent upon the teachers; they are to follow a certain prescribed course, without the privilege of the exercise of private judgment, and this course is in no case to be departed from;—100 lectures, and no less! But, for the students, they have only to procure the certificates as best they can—honestly if possible; but the certificates must be procured; and if only this can be done, it matters not one jot whether the lectures were ever attended or not.

How much more dignified and useful a system would it be if the medical authorities were to recognize certain schools only, such, for instance, as possessed the amplest capabilities for affording instruction, and instead of demanding certificates of having attended this course and that course, simply required that every student should enter at one of these schools, when his education would be under the control and direction of the professors and teachers of that school, who, at the expiration of a certain period, would certify that Mr. — had spent a number of years at — school, and was now fit to be examined for the diploma of the College of — ?

But, in my zeal to developen new scheme, I had almost forgotten the object of my present communication, namely, to inform you that the Professors of King's College have felt most anxious to carry into effect the system of noting the attendance of the students at lectures; they did actually keep up the practice for several years; and they

* Vide Mr. D. W. Harvey's regulations for omnibuses.

yielded to the request of many of their friends, to abandon the practice only because they found it impossible to obtain the support of those public bodies, from whom such a measure might well be expected to have originated. One of these bodies on having been applied to, to assist the efforts of the professors with their sanction and support, expressed themselves as follows:—"They regret that a plan so highly conducive to the regularity and efficiency of the studies at the medical schools as the daily registration of attendances, should be abandoned, but they have the utmost reliance that you will continue to satisfy yourselves of the correctness of your certificates."

It is plain that there is but one mode of ascertaining whether a student really deserves a certificate; *i. e.* has really and *bonâ fide* attended the course of lectures; and that mode is by registering his daily attendance; without some such means it is impossible for the teacher "to satisfy himself of the correctness" of the great majority of the certificates given to the students of a large class. It is evident, from the extract I have given, that the corporate body from whom the letter came, sees this, and entertains a high opinion of the advantages likely to result from it; but they refuse to enforce the system, or to sanction it in any way; and, what is very remarkable, they issued, immediately after they had sent the letter to which I refer, a new form of certificate, which certifies no more than that the student had entered to a certain course of lectures, and which a conscientious person would have no more difficulty in signing for a student who had attended only a single lecture, than for one who had been most diligent throughout the whole session.

It is at least satisfactory to feel that our legislators know what ought to be. We may live in hopes that one day they may become possessed of a sufficiency of moral courage to enable them to carry their present (presumed) good intentions into effect. Were I to offer a suggestion upon the subject, I should recommend simplicity of legislation. Strict laws respecting the admission of persons to become teachers, and the recognition of schools, would leave little more to be desired. Let it be the business of the schools, (the respectability of which would be guaranteed by the rigid enforcement of the laws just mentioned), to prepare the students in the best way they can for the degree or diploma examination. A salutary spirit of emulation will soon spring up among the schools, as soon as they shall have been relieved of the present absurd exactions of the corporate bodies, and when

they find themselves protected and encouraged by those bodies.

I remain, sir,

Your obedient servant.

A PROFESSOR AT KING'S COLLEGE,
LONDON.

December 4, 1838.

THE INFLUENZA AT LISBON.

By DR. LIMA LEITAO.

In the beginning of February the report spread in Lisbon that the influenza, which had been raging for several weeks in England, was on board several English ships lying at anchor in the Tagus. On the 20th of February the first cases occurred in the hospital, and at the same time the disease showed itself in the town, and attacked whole families. The reporter regrets that he can give no exact meteorological observations, having no instruments; he merely remembers in general, that until the end of December the winter was not severe; but that the first days of January were very cold, and on the 2d it snowed more than it had ever done in the memory of man, so that Lisbon, to the astonishment of its inhabitants, had the look of a town in the north of Europe. From the 10th of January, however, till the end of February, the sun shone warmly, although the wind blew strong and cold. He makes three degrees of the disease:—

First degree.—The usual symptoms of the first attack are followed by a burning in the throat, some hoarseness and dry cough, pain in the anterior part of the head, want of appetite, and thirst. This form of the disease lasted from four to six days, with mild evening exacerbations, the cough becoming moist, and nightly perspiration setting in.

Second degree.—In this form the well-known catarrhal symptoms were all incomparably more severe and obstinate, the cough more violent and more dry, with oppression of the chest and dyspnoea. The symptoms gradually grew milder, and the attack lasted from five to eight days.

Third degree.—The chest symptoms were not so prominent, but there was more affection of the head, amounting in some cases to lethargy. The duration of the disease in this form was the same.

General treatment.—This consisted of warm foot-baths, emollient clysters, and mild sudorifics, such as infusions of elder and poppy flowers; with soothing diet, and orange-water for drink. Only in cases where the oppression of the chest was very great, or the affection of the head and the

somnolence very violent, from ten to thirty ounces of blood were taken away at three times. Too vigorous a treatment with emetics, purgatives, and strong diaphoretics, and unseasonable bleeding, prolonged the disease.—*Zeitschrift für die gesammte Medicin*, for Oct. 1838, from the *Journal da Sociedade das Sciencias Medicas de Lisboa*.

CARBONIC ACID.

It is a decided fact that carbonic acid is one of the few remedies which are advantageous in all kinds of phthisis, whether mucous, suppurating, or serofulous, and which improve and lessen the expectoration, and make it easier, while they diminish the hectic fever; nay, this remedy has sometimes even produced a perfect cure. I appeal to my own experience as well as that of others, on the effects of Seltzer and similar simple carbonated waters.—*Hufeland: Praktische Uebersicht der vorzüglichsten Heilquellen Deutschlands*.

CHINESE HOSPITAL.

An hospital has been lately established at Canton, by an American surgeon and missionary, the Rev. P. Parker, for the gratuitous relief of afflicted Chinese. Several important operations have been performed, which have created considerable excitement among the Chinese, whose ignorance of surgery and medicine is said to be extreme. Such an institution may lead to the opening of an extended intercourse with the singular people, of which we as yet know so little.

COLLEGE OF SURGEONS.

GENTLEMEN WHO HAVE RECEIVED THEIR DIPLOMAS.

November, 1838.

T. J. Dyke, Merthyr, Glamorganshire.—C. B. Woods, Parson's Town.—T. Skeel, Norfolk Street, Strand.—J. B. Prowse, Bristol.—C. Nind, Beckham.—R. R. Oke, Southampton.—W. Heise, Peckham.—H. Fagg, Hampton Court.—W. A. Yates, Calcutta.—H. Avery, Monmouth.—H. Venn, Islington.—T. S. Lacy, Guernsey.—E. Howitt, Watworth.—F. M. Macpherson, Inverness.—H. E. Fripp, Bristol.—G. Redford, Worcester.—M. K. O'Shea, Dublin.—W. Pitt, London.—J. R. Ede, R.N.—G. P. Smith, Leeds.—W. E. Chilcote, Brixham, Devonshire.—B. S. Chimmo, Sheerness.—F. Danford, London.—C. Simpson, Stamford.—W. A. Rolfe, Norwich.—F. C. Malhaden, Fairfield, Manchester.—J. C. Young, Barbadoes.—J. R. Hancock, Sheerness.—R. W. Nelson, Dublin.—J. G. Hall, Swansea.—W. W. Mitchell, Keighley, York-shire.—W. S. Stanley, Dublin.—T. Sanderson, Bala, North Wales.—G. D. Harrison, Welchpool.—W. Prichard, Llandaff.
